ABSTRACT

This dissertation undertakes the theory and methods of sufficient dimension folding for matrix-/array-valued objects. Traditionally, researchers reduced the dimensions of matrix-/array-valued data by collapsing the data into vectorization. Nonetheless, analysis based on the vectorized data loses the crucial structural information carried by the data. Keeping the structure is critical in many fields. Dimension folding is a cutting-edge technology for capturing the critical essence of those structured data, reducing their dimensions as much as possible, yet preserving their intrinsic structure.

We first consider sufficient dimension folding for the regression mean function when predictors are matrix- or array-valued. A new concept central mean folding subspace and its two local estimation methods: folded outer product of gradients estimation (folded-OPG) and folded minimum average variance estimation (folded-MAVE) are proposed. The asymptotic property for folded-MAVE is established. A modified BIC criterion is used to determine the dimensions of the central mean folding subspace. Performances of the two local estimation methods are evaluated by simulated examples and the efficacy
is demonstrated in finite samples. The *folded-MAVE* method is adopted to analyze a primary biliary cirrhosis data set.

Second, we focus on sufficient dimension folding for regression on robustness for matrix- or array-valued objects. The *central functional folding subspace* and a class of estimation methods on robust estimators are introduced. Special attention is paid to the central quantile dimension folding subspace, a widely interesting case of the *central functional folding subspace*. The performances of the proposed estimation methods on estimating the central quantile folding dimension subspace are evaluated by simulated models. We also apply our method using quantile regression to the primary biliary cirrhosis data set.

Third, we introduce our future work. A class of dimension folding estimators based on an ensemble of *folded-MAVE* is introduced to characterize the central folding subspace (CFS). The ensemble estimators can exhaustively estimate the central folding subspace without imposing restrictive conditions on the predictors. A cross validation criterion is proposed to determine the dimensions of CFS. Theoretical properties and numerical performance of the proposed method will be studied in the future.

**INDEX WORDS:** Central Folding Subspace, Central Mean Folding Subspace, Central Quantile Folding Subspace, Folded Minimum Average Variance Estimation, Folded MAVE ensemble, Modified BIC criterion, Cross Validation.

Acknowledgments

I am deeply indebted to my major professor, Dr. Xiangrong Yin, for his generous help, encouragement and tremendous patience for the completion of this dissertation. Dr. Yin’s endless patience and kindness provide me with a pleasurable studying environment and numerous opportunities to engage with the statistical research community, such as attending workshops and conferences, referring on scientific articles and etc. Dr. Yin’s assistance extended beyond the usual requirement of the dissertation and provided significant help to my professional development.

I would like to extend my deepest thanks to my committee members Dr. Yehua Li, Dr. William McCormick, Dr. Cheolwoo Park, Dr. Jaxk Reeves and Dr. Lily Wang, for serving on my committee and their valuable suggestions and timely assistance in supporting my study at UGA.

My sincere appreciation is also extended to the faculty, staff and students of the Department of Statistics, who helped me in many ways and encouraged me to pursue my achievements in academics. In addition, I extend my special thanks to the faculty committee for providing me teaching assistantship and bring me to this great department in
2009. I am thankful for tremendous assistance provided by administrative staff at the department, with special thanks to Tim Cheek, Julie Davis and Daphney Smith.

Furthermore, I would like to thank Dr. William McCormick, Dr. Xiangrong Yin and Dr. Lily Wang for writing recommendation letters to support my job applications and giving me constructive career advice. I am also grateful for the tremendous support on my teaching assistant job provided by Dr. Jeongyoun Ahn, Dr. Gauri Datta, Dr. Nicole Lazar, Dr. Abhyuday Mandal, Dr. William McCormick, Dr. John Stufken, Dr. Xiangrong Yin, Dr. Lily Wang and many others. And I am grateful for the excellent teaching given by Dr. Daniel Hall, Dr. William McCormick, Dr. Lynne Seymour, Dr. Kimberly Love-Myers and many others. Their helps provide me solid foundation in methodology and theory in statistics and encourage me to attain this degree.

Finally, I would like to thank my family members for their encouragement, love and solicitude.

Chapter 1

Sufficient Dimension Folding for Regression Mean Function

1.1 Introduction

Modern data often have complex structures. For instance, matrix-valued predictors as in pictures, and array-valued predictors as in videos. Those data sets are large and structured, with each dimension representing different information in nature. Many traditional approaches are to vectorize matrix-/array-valued data so that methods that can efficiently analyze vector-valued predictors can be directly used. However, Li, Kim and Altman (2010) used electroencephalography (EEG) data to illustrate that vectorizing matrix-valued/array-valued predictors may lose sufficient information, data structure and related interpretation. In practice, treating the predictor as a matrix not only
can preserve the original matrix structure of the predictor and important aspects of interpretation, but also can reduce the number of parameters in dimension reduction estimation, which enhances the estimation accuracy. Dimension folding aims to reduce the matrix-/array-valued predictors as many as possible while preserving the structure interpretation of the underlying predictors. The sufficient dimension reduction subspace is a subset of dimension folding subspace. Except the information carried in dimension reduction subspace, the folding subspace also covers the information on data structure. Li, Kim and Altman (2010) introduced central dimension folding subspace for matrix- or array-valued objects and proposed three estimation techniques: folded-SIR, folded-SAVE and folded-DR. In this Chapter, we are interested in dimension folding for the regression mean function.

Our motivation is a primary biliary cirrhosis data set, available at http://lib.stat.cmu.edu/datasets/pbcseq. A group of predictors are repeatedly measured over time for 312 patients. If we view the group of predictors as one dimension of a matrix and the time line as another, then we would have a matrix formed predictor and each patient is a sample. In dimension folding we are interested in reducing the dimensions of such a matrix predictor along the row and column directions simultaneously. Thus, the correlations between the multivariate predictors across time are protected naturally.

To attain a more accurate estimator when the conditional mean is our interest, we introduce the central mean folding subspace (CMFS), which aims at the regression mean function only. We propose two local estimation methods for dimension folding: folded outer product of gradients estimation (folded-OPG) and folded minimum average vari-
ance estimation (*folded-MAVE*). The *folded-MAVE* does not require a strong assumption on the distribution of predictor; it can exhaustively recover the *central mean folding subspace*, and the estimation procedure can be broken down into iterations between several quadratic optimization steps, each of which has an explicit solution. A modified BIC criterion is used to determine the dimensions of the *central mean folding subspace*.

The remainder of the Chapter is organized as follows. In Section 1.2, we introduce the *central mean folding subspace* along with its properties. In Section 1.3, we introduce several estimation methods for the *central mean folding subspace*. In particular, we study the *folded-MAVE* and its property. Simulations and application are included in Section 1.4 and Section 1.5, respectively. A brief remark on array-valued predictors is presented in Section 1.6, followed by a short discussion in Section 1.7. We delay proofs to the Appendix.

### 1.2 Central mean dimension folding subspace

Let $\mathcal{S}(M)$ denote a subspace spanned by the columns of a matrix $M$ and let $P_M$ denote the orthogonal projection onto $\mathcal{S}(M)$, that is, $P_M = M(M^TM)^{-1}M^T$. We consider the regression of a univariate response $Y$ on a $p \times q$ random matrix $X$ and assume the data \( \{y_i, x_i\}, i = 1, \ldots, n \) are iid observations on $(Y, X)$. 
1.2.1 Overview of central folding subspace

Suppose there are two matrices $A \in \mathbb{R}^{p \times d}$ and $B \in \mathbb{R}^{q \times r}$, $d \leq p$ and $r \leq q$, such that

$$Y \parallel X \mid A^T XB.$$  (1.2.1)

Then $Y$ depends on $X$ only through $A^T XB$. The subspaces $\mathcal{S}(A)$ and $\mathcal{S}(B)$ are called a left- and right- dimension folding subspace for $Y \mid X$, respectively (Li, Kim and Altman, 2010). Under mild regularity conditions, the intersection of two left- or two right-dimension folding subspaces for $Y \mid X$ is itself a left- or right- dimension folding subspace. Let $\mathcal{S}_Y \circ X$ or $\mathcal{S}_Y \mid X_0$ be the intersection of all left- or right- dimension folding subspaces for $Y \mid X$. The subspace $\mathcal{S}_Y \mid X_0 \otimes \mathcal{S}_Y \mid 0 X$ is defined as the central dimension folding subspace (CFS) denoted by $\mathcal{S}_Y \mid 0 X_0$, where “$\otimes$” is the Kronecker product.

Let $\text{vec}(\cdot)$ be a vector operator defined by stacking the columns of a matrix “\cdot” into a vector, so that (1.2.1) is equivalent to $Y \parallel \text{vec}(X) \mid (B \otimes A)^T \text{vec}(X)$. Let $\mathcal{S}_Y \mid \text{vec}(X)$ be the central subspace (CS; Cook, 1994, 1996) of $Y$ with respect to the vector predictor $\text{vec}(X)$, so that $\mathcal{S}_Y \mid \text{vec}(X) \subseteq \mathcal{S}_Y \mid 0 X_0$. However, the opposite relation usually does not hold. Li, Kim and Altman (2010) claimed that $\mathcal{S}_Y \mid 0 X_0$ is the best way to reduce matrix-valued predictors if one hopes to preserve the matrix structure of $X$.

Li, Kim and Altman (2010) proposed the concept of Kronecker envelope. That is, for a random matrix $U \in \mathbb{R}^{(d_R d_L) \times k}$, suppose there are subspaces $\mathcal{S}_U \in \mathbb{R}^{d_R}$ and $\mathcal{S}_U \circ \in \mathbb{R}^{d_L}$
Then the smallest Kronecker product of the two subspaces that satisfy (1.2.2) is defined as the Kronecker envelope of $U$ (Li, Kim and Altman, 2010). The existence of a central dimension folding subspace follows from the results on the Kronecker envelope (Li, Kim and Altman, 2010; Theorems 1 and 2) and the existence of a central subspace (Cook, 1998; Yin, Li and Cook, 2008). Based on the Kronecker envelope, they constructed a general objective function and evaluated it using three different methods: folded-SIR, folded-SAVE and folded-DR, extending from the usual SIR (Li, 1991), SAVE (Cook and Weisberg, 1991) and DR (Li and Wang, 2007).

1.2.2 Central mean dimension folding subspace

Consider a regression model for dimension folding with matrix-valued predictors $X$ as

$$Y = f(A^T X B) + \epsilon,$$

(1.2.3)

where $f$ is an unknown link function, $A$ and $B$ are $p \times d$ and $q \times r$ orthogonal matrices with $d \leq p$ and $r \leq q$, and $E(\epsilon|X) = 0$ almost surely. The idea of dimension folding for a regression mean function can be briefly described as finding such matrices $A$ and $B$ that all the information about $Y$ carried in $E(Y|X)$ is covered by $A^T X B$. We formalize the model as follows.
**Definition 1.1.** Suppose there are matrices $A \in \mathbb{R}^{p \times d}$ and $B \in \mathbb{R}^{q \times r}$, $d \leq p$ and $r \leq q$, such that

\[
Y \perp E(Y|X)A^T XB.
\]

(1.2.4)

Then the space $S(A)$ or $S(B)$ is called a left- or right- mean dimension folding subspace.

If the intersection of all left- or right- mean dimension folding subspaces is itself a left- or right- mean dimension folding subspace, we can define the central mean folding subspace (CMFS) as:

**Definition 1.2.** Let $S_{E(Y|\circ X)}$ and $S_{E(Y|X_{\circ})}$ be the intersection of all left- or right- mean folding subspaces and itself is a left- or right- mean folding subspace for $E(Y|X)$, then $S_{E(Y|\circ X)}$ and $S_{E(Y|X_{\circ})}$ are defined as the central left- and right- mean dimension folding subspace respectively. Let $S_{E(Y|\circ X_{\circ})}$ denote the sufficient central mean dimension folding subspace. Then

\[
S_{E(Y|\circ X_{\circ})} = S_{E(Y|X_{\circ})} \otimes S_{E(Y|\circ X)}.
\]

(1.2.5)

The central mean folding subspace does not always exist, as the intersection of two left- or right- mean dimension folding subspaces is not always a left- or right- mean dimension folding subspace. Based on the conditions developed by Cook (1998), or Yin, Li and Cook (2008), together with Theorems 1 and 2 of Li, Kim and Altman (2010), one can show that the existence conditions of CMFS are the same as those of central mean subspace (CMS; Cook and Li, 2002). For instance, if the domain of $\text{vec}(X)$ is open and convex, then the CMFS exists and is unique. Since $Y \perp X|A^T XB$ implies
If \( Y \perp E(Y|X)A^TXB \), a dimension folding subspace is necessarily a mean dimension folding subspace. Once the CMFS exists, \( S_{E(Y|X)} \subseteq S_{Y|X} \) and \( S_{E(Y|\text{vec}(X))} \subseteq S_{E(Y|\text{vec}(X))} \), where \( S_{E(Y|\text{vec}(X))} \) is the CMS for \( \text{vec}(X) \). From here on, we assume \( A \in \mathbb{R}^{p \times d}, d \leq p \), is a basis matrix of \( S_{E(Y|X)} \) or \( S_{Y|X} \) and \( B \in \mathbb{R}^{q \times r}, r \leq q \), is a basis matrix of \( S_{E(Y|X)} \) or \( S_{Y|X} \) distinguished by whether the regression mean function is in focus or not.

The following proposition gives equivalent conditions for the conditional independence using Definition 1.1. We delay its proof to the Appendix.
Proposition 1.1. The following statements are equivalent:

1. \( Y \perp\!\!\!\perp E(Y|X)|A^TXB \)

2. \( \text{Cov}(Y, E(Y|X))|A^TXB] = 0 \)

3. \( E(Y|X) \) is a function of \( A^TXB \)

The central mean folding subspace is not invariant under one-to-one transformation of the response variable, because \( S_E(Y|\circ X_\circ) \) does not equal \( S_E(T(Y)|\circ X_\circ) \) in general. However, the following proposition shows that under affine linear transformation of the predictors, the central mean dimension folding subspace is invariant. Its proof is also delayed to the Appendix.

Proposition 1.2. Let \( Z = A_0^TXB_0 \) where \( A_0 \) and \( B_0 \) are full rank, \( p \times p \) and \( q \times q \) matrices respectively. Then \( S_E(Y|\circ Z_\circ) = (B_0^{-1} \otimes A_0^{-1})S_E(Y|\circ X_\circ) \).

1.3 Estimation of \( S_E(Y|\circ X_\circ) \)

In this section, we propose two main local estimation methods for the CMFS: folded-OPG and folded-MAVE. Before doing so, we introduce a technique to obtain a Kronecker product from a semi-orthogonal matrix, which will help us to obtain either an alternative solution if \( S_E(Y|\text{vec}(X)) = S_E(Y|\circ X_\circ) \), or better initial estimates in iterative folding approaches used later.
1.3.1 Matrix decomposition to a Kronecker product

Let $I_k$ be the $k$-dimensional identity matrix. Suppose $\eta \in \mathbb{R}^{pq \times dr}$ is a semi-orthogonal matrix (that is, $\eta^T \eta = I_{dr}$) such that $\eta = B^* \otimes A^*$, where $A^* \in \mathbb{R}^{p \times d}$ and $B^* \in \mathbb{R}^{q \times r}$ with $B^*^T B^* = I_r$ for identifiability. We will establish a decomposition method to obtain matrices $A^* \in \mathbb{R}^{p \times d}$ and $B^* \in \mathbb{R}^{q \times r}$. This decomposition technique bridges a way to estimate $S_Y|_X$ and $S_Y|_X^{|}$ or $S_E(Y|_X)$ and $S_E(Y|_X^{|})$ through $S_Y|_{\text{vec}(X)}$ or $S_E(Y|_{\text{vec}(X)})$.

Suppose such $\eta$ is a basis matrix for $S_Y|_{\text{vec}(X)}$, or $S_E(Y|_{\text{vec}(X)})$. In the first step, we estimate $\eta$ of $S_Y|_{\text{vec}(X)}$ or $S_E(Y|_{\text{vec}(X)})$; in the second step, we use the decomposition technique to estimate $A^*$ and $B^*$. When $S_Y|_{\text{vec}(X)} = S_Y|_{X^{|}}$ and $S_E(Y|_{\text{vec}(X)}) = S_E(Y|_{X^{|}})$, our algorithm can provide a solution of $S_Y|_{X^{|}}$ or $S_E(Y|_{X^{|}})$.

Let $\| \cdot \|$ be the Frobenius norm, so that the objective functions below are equivalent to ordinary least squares. Let $h_{ij}$ be the $i$-dimensional vector whose $j$-th element equals 1 and otherwise 0. Our procedure is as follow.

1. Generate the initial value of $A^*_{(0)} \in \mathbb{R}^{p \times d}$ from a sample of the $N(0,1)$ variables.

2. Given $A^*_{(k)}$, the estimate of $A^*$ in the $k$-th iteration, the $ij$-th element of $B^*_{(k)}$ in $k$-th iteration is the minimizer, $\hat{b}$, of the matrix norm

$$\|(h_{qi}^T \otimes I_p)\eta(h_{rj}^T \otimes I_d) - b A^*_{(k)}\|.$$

Then normalize $\hat{b}$ so that $B^*_{(k)}^T B^*_{(k)} = I_r$. 

9
3. Given $B_{(k)}^*$, the minimizer $\hat{a}$ of the objective function,

\[
|| (h_{pi}^T \otimes I_q)(\mathbb{K}_{p,q} \eta) \mathbb{K}_{r,d} (h_{dj} \otimes I_r) - aB_{(k)}^* ||,
\]

is the $ij$-th element of $A_{(k+1)}^*$ in the $(k+1)$-th iteration, where $\mathbb{K}$ is a commutation matrix. Its explicit form and the properties can be found in Magnus and Neudecker (1999). Here we use the property that: if $A^* \in \mathbb{R}^{p \times d}$ and $B^* \in \mathbb{R}^{q \times r}$, then $A^* \otimes B^* = \mathbb{K}_{p,q}(B^* \otimes A^*)\mathbb{K}_{r,d}$.

4. Check the convergence. Let $\tau(k) = B_{(k)}^* \otimes A_{(k)}^*$, $\tau(k-1) = B_{(k-1)}^* \otimes A_{(k-1)}^*$ be the estimates in the $k$-th and the $(k - 1)$-th iteration. If the discrepancy, $||\tau(k)\tau^T(k) - \tau(k-1)\tau^T(k-1)||$, is smaller than some pre-specified tolerance value, such as $10^{-6}$, then stop the iteration and set $\hat{A}^* = A_{(k)}^*$, $\hat{B}^* = B_{(k)}^*$; Otherwise, set $k = k + 1$ and proceed Step 2.

### 1.3.2 Local estimation methods of CMFS

At this stage, we assume that $d$ and $r$ are known. The key idea underlying the subsequent development of folded-OPG and folded-MAVE is as follows. Let $u = A^T X B$. Then, based on elementary calculations (Schott 1997), we have:

\[
\frac{\partial E(Y|X = x)}{\partial X} = \frac{\partial \text{vec}(u)^T}{\partial \text{vec}(X)} \cdot \frac{\partial E(Y|A^T X B = u)}{\partial \text{vec}(u)} = (B \otimes A) \cdot \frac{\partial E(Y|A^T X B = u)}{\partial \text{vec}(u)}.
\]
From the above, we know that \( \frac{\partial E(Y|X=x)}{\partial X} \in S(B \otimes A) = S_{E(Y|oX_o)} \). Thus, \( S_{E(Y|oX_o)} \) can be recovered by estimating the gradient of \( E(Y|X=x) \).

**folded-OPG**

The local polynomial smoothing (Fan and Gijbels, 1996) can be used to estimate the gradients. Here, for each \( j = 1, \ldots, n \), we consider the local linear fitting by minimizing the objective function,

\[
\sum_{i=1}^{n} [y_i - c_j - a_j^T(x_i - x_j)b_j]^2 w_{ij},
\]

over \( (c_j, a_j, b_j) \in \mathbb{R}^1 \times \mathbb{R}^p \times \mathbb{R}^q \), subject to \( b_j^T b_j = 1 \) where \( w_{ij} \geq 0 \) is the kernel weight centered at \( x_i - x_j \) with \( \sum_{i=1}^{n} w_{ij} = 1 \). We use the usual kernel weight:

\[
w_{ij}(h) = K_h(\text{vec}(x_i - x_j))/\sum_{j=1}^{n} K_h(\text{vec}(x_i - x_j)).
\]

For any \( v \in \mathbb{R}^p \), \( K_h(v) = h^{-p}K(||v||/h) \), where \( K(\cdot) \) is the chosen kernel function. In this chapter, we use the Gaussian kernel.

The **folded-OPG** based on minimizing (1.3.1) can be viewed as “weighted least squares” approach. For each \( j = 1, \ldots, n \), we can iteratively estimate \( a_j, b_j \) and \( c_j \). We suggest the following **folded-OPG** algorithm:

1. Generate the initial values of \( a_j \in \mathbb{R}^p \) for \( j = 1, \ldots, n \) from a sample of \( N(0,1) \) variables.
2. For fixed $a_j \in \mathbb{R}^p$, minimize (1.3.1) over $c_j$ and $b_j$ for $j = 1, \ldots, n$. The solution is

$$
\left( \hat{c}_j, \hat{b}_j \right) = \left[ \sum_{i=1}^{n} w_{ij}(h) \Delta_{ij}(a_j) \Delta_{ij}^T(a_j) \right]^{-1} \left[ \sum_{i=1}^{n} w_{ij}(h) \Delta_{ij}(a_j) y_i \right],
$$

where $\Delta_{ij}(a_j) = (1, (\text{vec}(x_i - x_j))^\top(I_q \otimes a_j))^\top$. Normalize $\hat{b}_j$: $\hat{b}_j^\top \hat{b}_j = 1$.

3. For fixed $c_j$ and $b_j$, let:

$$
\hat{a}_j = \left[ \sum_{i=1}^{n} w_{ij}(h) \Delta_{ij}(b_j) \Delta_{ij}^T(b_j) \right]^{-1} \left[ \sum_{i=1}^{n} w_{ij}(h) \Delta_{ij}(b_j)(y_i - c_j) \right],
$$

where $\Delta_{ij}(b_j) = (b_j \otimes I_p)^\top \text{vec}(x_i - x_j)$.

4. Check convergence. Let $A_{(k)}$, $B_{(k)}$ be the first $d$ or $r$ eigenvectors according to the $d$ or $r$ largest eigenvalues of $\sum_{j=1}^{n} \hat{a}_j \hat{a}_j^\top$ or $\sum_{j=1}^{n} \hat{b}_j \hat{b}_j^\top$ obtained in the $k$-th iteration respectively. Let $\tau_{(k)} = B_{(k)} \otimes A_{(k)}$, $\tau_{(k-1)} = B_{(k-1)} \otimes A_{(k-1)}$. If $\|\tau_{(k)} \tau_{(k)}^\top - \tau_{(k-1)} \tau_{(k-1)}^\top\|$ is smaller than some pre-specified tolerance value, such as $10^{-6}$, stop the iteration and set $A = A_{(k)}$, $B = B_{(k)}$; Otherwise, set $k = k + 1$ and proceed Step 2.

**folded-MAVE method**

The matrices $A \in \mathbb{R}^{p \times d}$ and $B \in \mathbb{R}^{q \times r}$ satisfying (1.2.3) are the minimizers of

$$
E[|Y - E(Y|A^\top XB)|^2],
$$

(1.3.2)
over $A$ and $B$, subject to $A^\top A = I_d$ and $B^\top B = I_r$. The conditional variance given $A^\top XB$ is

$$
\sigma^2_{A,B}(A^\top XB) = E[\{Y - E(Y|A^\top XB)\}^2|A^\top XB].
$$

(1.3.3)

Thus,

$$
\min_{A, B} E[Y - E(Y|A^\top XB)]^2 = \min_{A, B} E\{\sigma^2_{A,B}(A^\top XB)\}.
$$

(1.3.4)

At the sample level, for any given $x_0$, $\sigma^2_{A,B}(A^\top x_0B)$ can be approximated using local linear smoothing as

$$
\sigma^2_{A,B}(A^\top x_0B) \approx \sum_{i=1}^n \{y_i - E(y_i|A^\top x_iB)\}^2 w_{i0}
$$

$$
\approx \sum_{i=1}^n [y_i - c_0 - a_0^\top A^\top (x_i - x_0)Bb_0]^2 w_{i0},
$$

where $c_0 + a_0^\top A^\top (x_i - x_0)Bb_0$ is the local linear expansion of $E(y_i|A^\top x_iB)$ at the point $x_0$. Finding $A$ and $B$ is equivalent to solving the quadratic minimization

$$
\sum_{j=1}^n \sum_{i=1}^n \rho_j [y_i - c_j - a_j^\top A^\top (x_i - x_j)Bb_j]^2 w_{ij},
$$

(1.3.5)

over $(c_j, a_j, b_j, A, B) \in \mathbb{R}^1 \times \mathbb{R}^d \times \mathbb{R}^r \times \mathbb{R}^p \times \mathbb{R}^q$, subject to $b_j^\top b_j = 1$, $A^\top A = I_d$, $B^\top B = I_r$, for $i = 1, \ldots, n$ and $j = 1, \ldots, n$. We adopt coefficients $\{\rho_j : j = 1, \ldots, n\}$ to exclude unreliable samples with too few observations around $\rho(v) > 0$ if $v > v_0$ and $\rho(v) = 0$ if
\( v \leq v_0 \) for some small \( v_0 > 0 \). We take \( \rho_j = \rho(n^{-1} \sum_{i=1}^{n} K_{h_{(d,r)}}(\text{vec}(x_i - x_j)) \). Formula (1.3.5) is equivalent to

\[
\sum_{j=1}^{n} \sum_{i=1}^{n} \rho_j [y_i - c_j - (b_j \otimes a_j)^T (B \otimes A)^T \text{vec}(x_i - x_j)]^2 w_{ij}.
\] (1.3.6)

Minimizing the objective function (1.3.5) can be broken down into the following six-step iterative algorithm. And each minimization step is a quadratic optimization problem having an explicit solution. The \( \hat{A} \) and \( \hat{B} \) estimated by \textit{folded-OPG} method can be used as the initial value for \textit{folded-MAVE}. We set the kernel weights as

\[
w_{ij} = K_{h_{(d,r)}}(\text{vec}(\hat{A}^T(x_i - x_j)\hat{B}))/\sum_{j=1}^{n} K_{h_{(d,r)}}(\text{vec}(\hat{A}^T(x_i - x_j)\hat{B})).
\] (1.3.7)

The bandwidth \( h_{(d,r)} \) is set to be proportional to \( n^{-1/(dr+4)} \) (Silverman, 1986). Once an estimate of \( A \) or \( B \) is known, we use the existing estimate to update the bandwidth by formula (1.3.7) to reduce the dimension of the kernel function, which helps to carry out the smoothing over a lower dimension. That is, our \textit{folded-MAVE} method is similar to the refined MAVE (rMAVE; Xia, et al. 2002). More specifically, we define the \textit{folded-MAVE} algorithm as follows.

1. Generate the initial values of \( a_j \in \mathbb{R}^d \) for \( j = 1, \cdots, n \) from a sample of \( N(0,1) \) variables. Set the estimates \( \hat{A} \) and \( \hat{B} \) from \textit{folded-OPG} procedure as the initial values of \( A \) and \( B \).
2. For fixed $a_j \in \mathbb{R}^d$, $A \in \mathbb{R}^{p \times d}$, $B \in \mathbb{R}^{q \times r}$, minimize (1.3.5) over $c_j, b_j$ for $j = 1, \ldots, n$ subject to $b_j^T b_j = 1$. The solution is

$$
\left( \hat{c}_j, \hat{b}_j \right) = \left[ \sum_{i=1}^{n} \rho_j w_{ij}(h) \Delta_{ij}(a_j, A, B) \Delta_{ij}^T(a_j, A, B) \right]^{-1} \left[ \sum_{i=1}^{n} \rho_j w_{ij}(h) \Delta_{ij}(a_j, A, B) y_i \right],
$$

where $\Delta_{ij}(a_j, A, B) = (1, (\text{vec}(x_i - x_j))^T (B \otimes A)(I_r \otimes a_j))^T$.

3. For fixed $c_j \in \mathbb{R}^1$, $b_j \in \mathbb{R}^r$, $A \in \mathbb{R}^{p \times d}$, $B \in \mathbb{R}^{q \times r}$, minimize (1.3.5) over $a_j$ for $j = 1, \ldots, n$. Then,

$$
\hat{a}_j = \left[ \sum_{i=1}^{n} \rho_j w_{ij}(h) \Delta_{ij}(b_j, A, B) \Delta_{ij}^T(b_j, A, B) \right]^{-1} \left[ \sum_{i=1}^{n} \rho_j w_{ij}(h) \Delta_{ij}(b_j, A, B)(y_i - c_j) \right],
$$

where $\Delta_{ij}(b_j, A, B) = ((\text{vec}(x_i - x_j))^T (B \otimes A)(b_j \otimes I_d))^T$.

4. For fixed $c_j$, $a_j$, $b_j$ and $A$, the $\hat{B}$ that minimizes (1.3.5) is

$$
\text{vec}(\hat{B}) = \left[ \sum_{i,j=1}^{n} \rho_j w_{ij}(h) \Delta_{ij}(a_j, b_j, A) \Delta_{ij}^T(a_j, b_j, A) \right]^{-1} \left[ \sum_{i,j=1}^{n} \rho_j w_{ij}(h) \Delta_{ij}(a_j, b_j, A)(y_i - c_j) \right],
$$

where $\Delta_{ij}(a_j, b_j, A) = [I_r \otimes ((x_i - x_j)^T A)](b_j \otimes I_d)$. Normalize $\hat{B}$ so that $\hat{B}^T \hat{B} = I_r$.

5. For fixed $c_j$, $a_j$, $b_j$ and $B$, the $\hat{A}$ that minimizes (1.3.5) is

$$
\text{vec}(\hat{A}^T) = \left[ \sum_{i,j=1}^{n} \rho_j w_{ij}(h) \Delta_{ij}(a_j, b_j, B) \Delta_{ij}^T(a_j, b_j, B) \right]^{-1} \left[ \sum_{i,j=1}^{n} \rho_j w_{ij}(h) \Delta_{ij}(a_j, b_j, B)(y_i - c_j) \right],
$$

where $\Delta_{ij}(a_j, b_j, B) = [((x_i - x_j)B) \otimes I_d](b_j \otimes I_d)$. Normalize $\hat{A}$ so that $\hat{A}^T \hat{A} = I_d$. 

15
6. Check convergence. Let $A_{(k)}$, $B_{(k)}$ be the estimator of $A$ and $B$ obtained in the $k$-th iteration, respectively. Let $\tau_{(k)} = B_{(k)} \otimes A_{(k)}$, $\tau_{(k-1)} = B_{(k-1)} \otimes A_{(k-1)}$. If $||\tau_{(k)}^T \tau_{(k)} - \tau_{(k-1)}^T \tau_{(k-1)}||$ is smaller than some pre-specified tolerance value, such as $10^{-6}$, stop the iteration and set $A = A_{(k)}$, $B = B_{(k)}$; Otherwise, set $k = k + 1$ and proceed Step 2.

1.3.3 Sampling property

In this section, we will investigate the sampling property of our estimator, similar to those made in Xia (2007), and Wang and Xia (2008). In particular, we follow the proofs in Yin and Li (2011).

Let $g(\cdot)$ be a generic density. Let $A$ and $B$ be the corresponding semi-orthogonal bases for the cental left- and right- mean folding subspace. Suppose that $A_*$ and $B_*$ are generic $p$-row and $q$-row matrices, respectively. We assume the following conditions:

(C1) [Marginal distribution of vec($X$)] The covariate vec($X$) is bounded; its density function $g(\text{vec}(X))$ has bounded second order derivatives; functions

$$
\mu_{B_* \otimes A_*}(u) = E(\text{vec}(X) | (B_* \otimes A_*)^T \text{vec}(X) = u),
$$

$$
\omega_{B_* \otimes A_*}(u) = E(\text{vec}(X) \text{vec}(X)^T | (B_* \otimes A_*)^T \text{vec}(X) = u)
$$

have bounded derivatives with respect to $u$, and $B_* \otimes A_*$ for $B_* \otimes A_* \in \{B_* \otimes A_* : ||(B_* \otimes A_*)(B_* \otimes A_*)^T - (B \otimes A)(B \otimes A)^T|| \leq c^*\}$ for some $c^* > 0$. 

16
(C2) [Conditional distribution function of $Y$ given $(B \otimes A)^T \text{vec}(X)$] The conditional density function $g(Y|u)$ has bounded fourth order derivatives with respect to $\text{vec}(X)$, $u$ and $B \otimes A$. as $B \otimes A$ is in a small neighbor of $B \otimes A$.

(C3) [Central mean folding subspace] For any semi-orthogonal $p \times d_*$ matrix $A_*$ and semi-orthogonal $q \times r_*$ matrix $B_*$ and constant $c^* > 0$, if $B_* \otimes A_* : ||(B_* \otimes A_*)(B_* \otimes A_*)^T - (B \otimes A)(B \otimes A)^T|| \geq c^*$, then

$$\inf_{B_* \otimes A_*} E[E(Y|A_*^TXB_*) - E(Y|A^TXB)]^2 > 0.$$  

(C4) [Kernel function] Function $K_0(\cdot)$ is a symmetric univariate density function with bounded second order derivative and compact supports.

(C5) [Bandwidths] For working dimension $d$ and $r_*$, the bandwidths $\{h_k : k = 0, 1, \ldots\}$ satisfy $h_0 \propto n^{-1/(pq+4)}$, $h_t = \max\{\varsigma h_{t-1}, h\}$ with $1/2 < \varsigma < 1$, and $h \propto n^{-1/(d_\*r_*+4)}$.

The general idea of the proof is the following: Note that (1.3.5) is equivalent to

$$\sum_{j=1}^{n} \sum_{i=1}^{n} \rho_j [y_i - c_j - (b_j \otimes a_j)^T(B \otimes A)^T \text{vec}(x_i - x_j)]^2 w_{ij}. \quad (1.3.8)$$

Defining $B = B \otimes A$, $d_j = b_j \otimes a_j$, $X = \text{vec}(X)$, $X_i = \text{vec}(x_i)$ and $X_{ij} = \text{vec}(x_i - x_j)$, (1.3.8) transforms to

$$\sum_{j=1}^{n} \sum_{i=1}^{n} \rho_j [y_i - c_j - d_j^T B^T X_{ij}]^2 w_{ij}. \quad (1.3.9)$$
Note that formulation (1.3.9) is exactly what Yin and Li (2011) had for the objective function, if we set, \( f(y_i) = y_i \) and \( m = 1 \). In such a case, when the central mean subspace of \( \text{vec}(X) \) is the same as that of the folding subspace, estimate \( \hat{B} \) is the weighted least squares solution as in Yin and Li (2011). Hence, the asymptotic results follow immediately. However, when the central mean subspace of \( \text{vec}(X) \) is not the same as that of the folding subspace, estimating \( B \) directly by the weighted least squares method will return basis matrix for other subspaces rather than the central mean folding subspace, generally a subspace of folding space if dimensions are assumed correctly to the ones for the central mean subspace. To prevent the latter, we notice that the Kronecker product structure of \( B \) can be recovered by using the iteration methods we proposed previously. Thus the final estimate, \( \hat{B} = \hat{B} \otimes \hat{A} \), is then the weighted least squares solution of (1.3.9) with such a structure. Therefore, we can prove the asymptotic result exactly following proof in Yin and Li (2011). Suppose \( \hat{A}_* \) and \( \hat{B}_* \) are the corresponding estimates of \( A_* \) and \( B_* \). Then the following theorem gives the convergence rate of folded-MAVE when \( d_* = d \) and \( r_* = r \), whose proof will be provided upon request.

**Theorem 1.1.** Suppose conditions (C1)–(C5) hold, \( d_* = d \), \( r_* = r \) and the final bandwidth is \( h \), then the folded-MAVE estimator \( \hat{B} \otimes \hat{A} \) is consistent with,

\[
|| (\hat{B} \otimes \hat{A})(\hat{B} \otimes \hat{A})^T - (B \otimes A)(B \otimes A)^T || = O_P\{h^4 + \log n/(nh^{dr}) + n^{-1/2}\}.
\]
1.3.4 Estimation of the CMFS dimension

Previously, we assumed that \(d\) and \(r\) are known, but typically we don’t know either \(d\) or \(r\). Thus, an estimation method for \(d\) and \(r\) is needed. In this section, we propose a modified BIC criterion to estimate \(d\) and \(r\) for folded-MAVE.

For vector predictors, Xia et al. (2002) proposed a Cross Validation (CV) criterion. Zhu, Miao and Peng (2006) proposed several BIC criteria to determine the dimension of CS. Wang and Yin (2008) suggested a modified BIC criterion for Sparse MAVE. Following Wang and Yin (2008), we propose our modified BIC criterion to estimate \(d\) and \(r\) as follows:

\[
BIC_{(d_*,r_*)} = \log\left(\frac{RSS_{(d_*,r_*)}}{n}\right) + \frac{C_n \times d_* r_*}{nk_{(d_*,r_*)}},
\]

where \(1 \leq d_* \leq p, 1 \leq r_* \leq q\), \(C_n > 0\), and \(RSS_{(d_*,r_*)}\) is the residual sum of squares from the local linear smoothing using semi-orthogonal \(p \times d_*\) matrix \(\hat{A}_{d_*}\) and semi-orthogonal \(q \times r_*\) matrix \(\hat{B}_{r_*}\). That is, let \(x_{ij} = x_i - x_j\), then

\[
RSS_{(d_*,r_*)} = \sum_{j=1}^{n} \sum_{i=1}^{n} (y_i - \hat{c}_j - \hat{a}_j^T \hat{A}_{d_*} x_{ij} \hat{B}_{r_*} \hat{b}_j)^2 K_{h_{(d_*,r_*)}}(\text{vec}(\hat{A}_{d_*} x_{ij} \hat{B}_{r_*})).
\]

The estimated dimensions are then

\[
(\hat{d}, \hat{r}) = \min\{(d_*, r_*) : (d_*, r_*) = \arg\min_{1 \leq d_* \leq p, 1 \leq r_* \leq q} \{BIC_{(d_*,r_*)}\}\}.
\]

We have the following result, and its proof is in the Appendix.
Proposition 1.3. Under the assumptions in the Appendix, \((\hat{d}, \hat{r}) \to (d, r)\), in probability.

We use the bandwidth, \(h_{(d^*, r^*)} = n^{-1/(4 + d^* r^*)}\), similar to that of Wang and Yin (2008). For the BIC criterion, we used \(C_n = W_n = (.5 \log(n) + .1 n^{1/3})/2\) (Zhu, Miao and Peng, 2006). In such a case if \(dr < 8\), Proposition 1.3 holds, so that \((\hat{d}, \hat{r}) \to (d, r)\), in probability. Indeed, in our simulated models, \(dr = 4\) or \(dr = 2\), so results showed what we expected.

1.3.5 The standardization of \(X\)

When the scales of the elements of \(X\) are different, estimates using the original scales may not be accurate. To eliminate such an effect, we may need to standardize \(X\) before estimating its central folding subspace or central mean folding subspace. However, since \(X\) is a matrix, the standardization encounters some difficulties. It involves the estimation of the Kronecker product structure of the covariance matrix, \(\Sigma = \text{Cov}(\text{vec}(X))\). That is, \(\Sigma\) is said to be \((q, p)\)-separable (Lu and Zimmerman, 2005) if \(\Sigma = \Sigma_r \otimes \Sigma_l\), where \(\Sigma_r\) is \(q \times q\) and positive definite, and \(\Sigma_l\) is \(p \times p\) and positive definite. If \(\text{vec}(X)\) follows a multivariate normal distribution with mean \(\text{vec}(U)\), where \(U\) is the mean of \(X\), and the covariance matrix \(\Sigma = \Sigma_r \otimes \Sigma_l\), we use the notation

\[ X \sim N_{p,q}(U, \Sigma_l, \Sigma_r) \]
to stand for the distribution of the random matrix $X$ (Srivastava, von Rosen and von Rosen, 2008).

Under the matrix normal distribution model $N_{p,q}(U, \Sigma_l, \Sigma_r)$, Dutilleul (1999), Lu and Zimmerman (2005) and Roy and Khattree (2005) proposed the maximum likelihood estimation (MLE) for $U$, $\Sigma_l$ and $\Sigma_r$ using an iterative “flip-flop” scheme (Mardia and Goodall, 1993; Dutilleul, 1999; Brown, Kenward and Bassett, 2001), alternating between the estimates of $\Sigma_l$ and $\Sigma_r$. However, since $\Sigma = (c\Sigma_r) \otimes (c^\top \Sigma_l)$ for any non-zero constant $c$, the estimates of $\Sigma_l$ and $\Sigma_r$ are not unique if there is no restriction on $\Sigma_l$ or $\Sigma_r$ except for positive definiteness (Lee, Dutilleul and Roy, 2010).

Suppose $x_1, \ldots, x_n$ are $n$ iid sample from $N_{p,q}(U, \Sigma_l, \Sigma_r)$ with $n > \max(p, q)$. Let $x_{(i)j}$ be the $i$-th column vector and $x_{(k)j}$ be the $k$-th row for the $j$-th sample $x_j$. Then we can rewrite $x_j$ into $x_j = (x_{(1)j}, \ldots, x_{(q)j})$, where $x_{(1)j}, \ldots, x_{(q)j}$ are $p \times 1$ column vectors, or $x_j = (x_{(1)j}^\top, \ldots, x_{(p)j}^\top)^\top$, where $x_{(1)j}, \ldots, x_{(p)j}$ are $1 \times q$ row vectors, for $j = 1, \ldots, n$. Let $\bar{X} = \frac{1}{n} \sum_{j=1}^n x_j$ then $\bar{X} = (\bar{x}_{(1)}, \ldots, \bar{x}_{(q)})$ or $\bar{X} = (\bar{x}_{(1)}^\top, \ldots, \bar{x}_{(p)}^\top)^\top$.

By constraining the on-diagonal elements in $\Sigma_r$ to be 1, Srivastava, von Rosen and von Rosen (2008) constructed the unique MLE of $U$, $\Sigma_l$, and $\Sigma_r$ as: $\hat{U} = \bar{X}, \hat{\Sigma}_l = S = \frac{1}{nq} \sum_{j=1}^n (x_j - \bar{X})(x_j - \bar{X})^\top$. For the $(i, k)$-th entry, $\sigma_{i,k}$, in $\Sigma_r$, where $i \neq k$:

$$
\hat{\sigma}_{i,k} = \frac{1}{nq} \sum_{j=1}^n \text{tr}(S^{-1}(x_{(i)j} - \bar{x}_{(i)})(x_{(i)j} - \bar{x}_{(i)})^\top),
$$

where $\text{tr}(\cdot)$ stands for the trace of a matrix. Note that $\frac{n}{n-1} S$ is an unbiased and consistent estimator of $\Sigma_l$, and $\hat{\sigma}_{i,k}$ is a consistent estimator of $\sigma_{i,k}$.
Pfeiffer, Forzani and Bura (2011) provided different estimators for $\Sigma_l$ and $\Sigma_r$. Assuming there are no missing value, in $\mathbf{X}$, then their estimators are:

$$\hat{\Sigma}_{lt} = \frac{1}{n} \sum_{j=1}^{n} (x_{(t)}j - \bar{x}_{(t)})(x_{(t)}j - \bar{x}_{(t)})^T, \quad \hat{\Sigma}_l = \frac{1}{q} \sum_{t=1}^{q} \hat{\Sigma}_{lt},$$

and

$$\hat{\Sigma}_{rk} = \frac{1}{n} \sum_{j=1}^{n} (x_{(k)}j - \bar{x}_{(k)})(x_{(k)}j - \bar{x}_{(k)})^T, \quad \hat{\Sigma}_r = \frac{1}{p} \sum_{k=1}^{p} \hat{\Sigma}_{lk}.$$ 

Likelihood ratio tests for the separability of $\Sigma$ can be found in Lu and Zimmerman (2005), Roy and Khattree (2005) and Srivastava, von Rosen and von Rosen (2008, 2009). Our simulations show that the above two methods for estimating the Kronecker product of the covariance matrix are equivalent, and we adopt Pfeiffer’s method.

Without confusion, let $\mathbf{Z}$ be the standardization of $\mathbf{X}$ and $\mathbf{z}_i$ be the $i$-th sample of $\mathbf{Z}$. We normalize the $i$-th sample of $\text{vec}(\mathbf{X})$ as $\text{vec}(\mathbf{z}_i) = \hat{\Sigma}_{l}^{-1/2}(\text{vec}(\mathbf{x}_i) - \text{vec}(\bar{\mathbf{x}})) = (\hat{\Sigma}_r \otimes \hat{\Sigma}_l)^{-1/2}(\text{vec}(\mathbf{x}_i) - \text{vec}(\bar{\mathbf{x}}))$. Thus $\mathbf{z}_i = \hat{\Sigma}_l^{-1/2}(\mathbf{x}_i - \bar{\mathbf{x}})\hat{\Sigma}_r^{-1/2}$. Suppose the bases for the corresponding central left- and right- mean dimension folding subspaces of $\mathbf{Z}$ are $A_Z$ and $B_Z$, then we transform the bases back to the $\mathbf{X}$ scale as $\hat{\Sigma}_{l}^{-1/2} A_Z$ and $\hat{\Sigma}_r^{-1/2} B_Z$ for the central left- and central right mean dimension folding subspaces, respectively.
1.4 Numerical Study

To evaluate the accuracy of estimates of our methods, we use the distance proposed by Li, Zha and Chiaromonte (2005),

$$\Delta(B \otimes A, \hat{B} \otimes \hat{A}) = ||P_{B \otimes A} - P_{\hat{B} \otimes \hat{A}}||.$$  

We use the Frobenius norm $|| \cdot ||$ and denote it by $\Delta_f$. The smaller the $\Delta_f$ is, the better the estimate is. In addition, we also use the benchmark distance provided by Li, Wen and Zhu (2008) to understand the accuracy of the estimates. Let $\alpha$ and $\beta$ be $s \times t$ random matrices whose entries are independent random variables each with a standard normal distribution, satisfying $\alpha \perp \beta$. Let $P_\alpha$ and $P_\beta$ be the projections onto the column space of $\alpha$ and $\beta$ separately. The benchmark distance, $E(||P_\alpha - P_\beta||)$, is determined only by the values of $s$ and $t$. We estimate the benchmark distance by running 10,000 simulations and denote it by $\Delta_B$.

We use $p = q = 5$ in the simulated examples. The error $\epsilon$ is independent of $X$ and follows a standard normal distribution. In order to compare with the fold-SIR, folded-SAVE and folded-DR, all the models we construct satisfy $S_{Y|oX_o} = S_{E(Y|oX_o)}$. In the first four examples, the predictor $\text{vec}(X) \sim N_{pq}(0, I_{pq})$. In Example 1.5, we consider a correlated predictor model, where $\text{vec}(X) \sim N_{pq}(0, \Sigma_{\text{vec}(X)})$ and $\Sigma_{\text{vec}(X)}$ is a $pq \times pq$ positive definite matrix with $(j_1, j_2)$-th entry $0.5^{j_1-j_2}$. We run 100 replicates for each model and compute the average of $\Delta_f$ and its standard error, and report the accuracy
as: mean ± standard deviation. Let $e_1 = (1, 0, 0, 0)^T$ and $e_2 = (0, 1, 0, 0)^T$. Further, we write $X_{ij}$ as the random predictor in the $ij$-th position of $X$.

**Example 1.1.** $Y = X_{11} \times (X_{12} + X_{21} + 1) + 0.2 \times \epsilon$.

In this example, $\mathcal{S}_{Y|\circ X\circ} = \mathcal{S}_{E(Y|\circ X\circ)} = \mathcal{S}(e_1 \otimes e_1, e_1 \otimes e_2, e_2 \otimes e_1, e_2 \otimes e_2)$ with $d = r = 2$; while $\mathcal{S}_{Y|\text{vec}(X)} = \mathcal{S}_{E(Y|\text{vec}(X))} = \mathcal{S}(e_1 \otimes e_1, e_1 \otimes e_2 + e_2 \otimes e_1)$. Obviously, $\mathcal{S}_{Y|\text{vec}(X)} = \mathcal{S}_{E(Y|\text{vec}(X))} \subset \mathcal{S}_{Y|\circ X\circ} = \mathcal{S}_{E(Y|\circ X\circ)}$. For this example, the two-step decomposition method in Section 1.3.1 can not exhaustively recover the CMFS. To demonstrate the performance of the two-step method in estimating CMFS of $X$, we first apply the OPG method to $\text{vec}(X)$ and then decompose the estimated base into a Kronecker product of two matrices as described in Section 1.3.1. Table 1 shows that the two-step decomposition method (“two-step”) fails in recovering the central mean folding subspace. The rMAVE for $\text{vec}(X)$ also fails to recover the CMFS as shown in Table 1.1. The folded-OPG and folded-MAVE dominate the folded-SIR, folded-SAVE and folded-DR, while folded-MAVE performs the best among all these methods. With sample size increasing, the accuracy of estimating CMFS is improved. The benchmark distance is $\Delta_B = 2.586$.

</table>

Example 1.2. : \( Y = X_{11}/\{0.5 + (X_{21} + 1.5)^2\} + 0.5 \times \epsilon \).

Example 1.2 is a model whose corresponding vector version is favored by SIR (Li, 1991; Xia, et al. 2002). Here, \( S_{Y|x_0} = S_{E(Y|x_0)} = S_{E(Y|\text{vec}(X))} = S_{E(Y|\text{vec}(X))} = S(e_1 \otimes e_1, e_1 \otimes e_2) \) and \( d = 2, r = 1 \). Thus, unlike Example 1, estimating the CMFS through the two-step decomposition method or CMS of the \( \text{vec}(X) \) by rMAVE can recover the dimension folding subspace. And again, we use the two-step method based on OPG, and rMAVE using \( \text{vec}(X) \). Since more parameters need to be estimated, the estimates of “two-step” approach and rMAVE are less accurate than folded-OPG and folded-MAVE shown in Table 1.2, as expected. The benchmark distance for this example is \( \Delta_B = 1.916 \). And once again, folded-MAVE dominates other folded methods.

Example 1.3. : \( Y = X_{11} + (X_{21} + X_{22})^2 + 0.5 \times \epsilon. \)

Let \( e_{12} = e_1 + e_2. \) In this example, \( \mathcal{S}_{Y|\phi X_0} = \mathcal{S}_{E(Y|\phi X_0)} = \mathcal{S}(e_1 \otimes e_1, e_1 \otimes e_2, e_{12} \otimes e_1, e_{12} \otimes e_2) = \mathcal{S}(e_1 \otimes e_1, e_1 \otimes e_2, e_2 \otimes e_1, e_2 \otimes e_2). \) This model contains both a linear term and a quadratic term, \( d = r = 2 \) and \( \Delta_B = 2.586. \) Table 1.3 shows that folded-MAVE is the best, followed by folded-OPG and folded-DR. It appears that folded-SIR and folded-SAVE miss the folding subspace, which may be expected, as folded-SIR will miss the quadratic term while folded-SAVE may miss the linear term.

Example 1.4. \[ Y = X_{11} + 2 \times X_{21}^2 + 3 \times X_{12}^2 + 4 \times X_{22}^2 + 0.2 \times \epsilon. \]

This example is a modified model of Wang and Yin (2008). Here, \( d = r = 2 \) and \( \Delta_B = 2.586 \), and \( S_{Y|\circ X_o} = S_{E(Y|\circ X_o)} = S(e_1 \otimes e_1, e_1 \otimes e_2, e_2 \otimes e_1, e_2 \otimes e_2) \). Since there are more quadratic terms in the model, it is expected that folded-SAVE’s performance will be better than that of folded-SIR. In fact, as shown in Table 1.4, folded-SAVE and folded-DR are better than that of the folded-OPG, but folded-MAVE is still the best.

Example 1.5. \[ Y = X_{11} \times (X_{12} + X_{21} + 1) + 0.2 \times \epsilon. \]

This is Example 1.1, but with \( \text{vec}(X) \sim N_{pq}(0, \Sigma_{\text{vec}(X)}) \), where \( \Sigma_{\text{vec}(X)} \) is a \( pq \times pq \) positive definite matrix with \((j_1, j_2)\)-th entry \( 0.5^{|j_1-j_2|} \). Thus the predictor variables are moderately correlated. Table 1.5 indicates that folded-OPG and folded-MAVE work well, and both are better than the folded-SIR, folded-SAVE and folded-DR when \( S_{Y|\circ X_o} \) coincides \( S_{E(Y|\circ X_o)} \). The respective estimates, are as expected, found to be less accurate than that of the model with independent variables shown in Example 1.1.

Example 1.6. : Signal-ratio study

We check the changes of the performance of our folded-MAVE method based on the signal-noise ratio for Example, 1.1, 1.2, 1.3 and 1.4. The error term $\epsilon$ follows a standard normal distribution. We apply a series of signal-noise ratios to the first four models and fit the change trend. We run Example 1.1 and 1.3 with the noise terms: $0.2\epsilon$, $0.5\epsilon$, $\epsilon$, $1.5\epsilon$, $2\epsilon$, $2.5\epsilon$, $3\epsilon$, $4\epsilon$, $6\epsilon$, $8\epsilon$, $10\epsilon$. And for Example 1.2, we choose noise terms: $0.2\epsilon$, $0.5\epsilon$, $\epsilon$, $1.5\epsilon$, $2\epsilon$, $2.5\epsilon$, $3\epsilon$, $4\epsilon$, $6\epsilon$, $8\epsilon$, $9\epsilon$. The estimation for Example 1.4 is more accurate comparing to the other 3 models for large errors. Thus we apply noise terms $0.5\epsilon$, $\epsilon$, $2\epsilon$, $4\epsilon$, $6\epsilon$, $8\epsilon$, $10\epsilon$, $12\epsilon$, $16\epsilon$, $20\epsilon$ and $24\epsilon$ to Example 1.4. Figure 1.1 shows as the error increases, the average of $\Delta_f$ increases, which indicates less accuracy. And lager sample size $n$ helps to enhance the estimation accuracy.
Figure 1.1: Change of the average of $\Delta f$ as error increases
Table 1.6 reports the percentage of the correctly estimated dimensions by our modified BIC criterion. With sample size increasing, for each example, the accuracy of correctly estimated \((d, r)\) is improved. The performance of the modified BIC is also less accurate for correlated data (Example 1.5) than that in the corresponding model with independent variables (Example 1.1). Nevertheless, the modified BIC criterion works well in these limited simulations.

Table 1.6: Percentage of correctly estimate \(d\) and \(r\) using the modified BIC criterion.

1.5 Application

In this section, we analyze part of the longitudinal data from the follow-up to a Mayo Clinic trial on primary biliary cirrhosis (PBC). The follow-up was conducted between 1974 and 1984 and its description can be found in Fleming & Harrington (1991) and Murtaugh et al. (1994). The data we used are available at http://lib.stat.cmu.edu/datasets/pbcseq. The data set contains multiple laboratory results for 312 patients. Primary biliary cirrhosis is a chronic, progressive cholesteric liver disease of adults that leads to liver failure and the need of transplantation or death (Talwalkar and K. D Lindor, 2003). Several biomarkers such as biliribin, albumin and prothrombin time are adopted to diagnose PBC. Müller (2005) investigated the PBC data from the Mayo Clinic trail to predict
the long-term survival as function of the repeated longitudinally recorded level of serum bilirubin. Albert and Shih (2010) proposed an approach for jointly modeling multiple longitudinal measurements and discrete time-to-event data. They applied their method to verify whether the biomarkers are prognostic for the time to either liver transplantation needed or death. Those two papers worked on the log-transformed measurements of the covariates. Kim et al. (2000) presented an abbreviated model to assess the PBC disease risk score based on the measured level of bilirubin, albumin and other markers.

We work on the PBC data from the aspect of dimension folding. We treat the time baseline as one fold of covariates, and the multivariate predictors repeatedly measured over time as another fold of covariates and thus we have a matrix formed predictor. folded-MAVE can reduce the dimensions on both folds at the same time as much as possible without losing any information and protect the longitudinal structure of the predictors as well. We concentrate our attention on the measurement of bilirubin, albumin level and prothrombin time at time point: 6-month, 1-year, 2-year and 3-year so that the predictor is a $3 \times 4$ random matrix.

The response is the time in years between registration and the earlier of transplanting or death. We treat visits between day 90 and day 270 from the enrollment as in the group at time point 6-months. Visits between day 270 and day 550, between day 550 and day 910, between day 910 and day 1275 from the enrollment are identified as at time point 1-year, 2-year and 3-year, respectively. There are 187 patients who had full record at those four time points. However, some patients whose transplant-free or survival time
approximates but is less than 3 years are also considered in the analysis, as long as they visited at the four time points.

Sufficient dimension reduction for the analysis of longitudinal data was first used by Li and Yin (2009). They treated time as a discrete random variable. Conditioning on time, they suggested a partial ordinary least squares method, which is an analogy of the partial OLS method in Li, Cook and Chiaromonte (2003), to estimate the partial central mean subspace and then combined all the partial central mean subspaces together. However, their method missed the correlation structure among different time points. Pfeiffer, Forzani and Bura (2011) proposed a longitudinal version of sliced inverse regression (LSIR) to reduce the dimensions of longitudinally measured predictor by assuming that the first and second moments of the predictors can be decomposed into a time and a marker component via a Kronecker product structure. LSIR takes the correlation across time into account, but it requires the assumption of a linearity condition and it can not exhaustively estimate the directions for binary outcomes. The folded-MAVE method considers the longitudinal data as a matrix, and the correlations among the structure.

By applying the modified BIC criterion to the data, we have \( \hat{d} = \hat{r} = 1 \). The estimated bases for the left- and right- mean folding subspaces in the \( X \)-scale are \( A_X = (\alpha_1, \alpha_2, \alpha_3)^T = (0.11029205, -0.99246655, -0.05334607)^T \) and \( B_X = (\beta_1, \beta_2, \beta_3, \beta_4)^T = (-0.2277369, -0.2320542, -0.1827723, -0.9278367)^T \). To test the significance of each coefficient in \( A_X \) and \( B_X \), we compute the 95% bootstrap confidence intervals of \( A_X \) and \( B_X \) with 1000 bootstrap samples. Table 1.7 indicates the confidence intervals that
show, at 0.05 level, serum bilirubin and albumin level at year 3 significantly affect the length of the time between registration and the earlier of transplanting or death.

The plot of the top panel in Figure 1.2 shows the summary plot. That is, the response versus the reduced predictor. Taking the minus sign in $B_X$ into account, bilirubin has a negative relationship and albumin level has a positive relationship with the transplant-free or survival time, which is consistent with the already known medical outcome (Shapiro, Smith and Schaffner, 1979). Time point year 3 contributed significantly to the time component, which shows the progressive nature of the disease.

The *folded-MAVE* allows us to assess longitudinal regression in a low-dimensional circumstance. Next we fit a regression model based on the reduced data using the smoothing spline method with degree of freedom 4 and the smoothing parameter $\lambda = 0.01842554$ (Fan and Yao, 2003). The fitted smoothing spline is the imposed curve on the top panel in Figure 1, while the residual against the fitted response is on the bottom panel in Figure 1.2. The regression fit appears adequate and the residual plot shows the model is very reasonable.

1.6 Generalization to array-valued predictors

In this section, we briefly discuss how to extend the theory and methodology for the matrix-valued predictors to array-valued predictors. Let $X = \{X_{j_1j_2...j_k} : j_1 = 1, \ldots, p_1, \ldots, j_k = 1, \ldots, p_k \}$ be a $k$-way random array of dimension $p_1 \times \cdots \times p_k$. Parallel to Definition 1.1, we define the following:

**Definition 1.3.** If there are $p_i \times d_i$ matrices $\alpha_i$ ($d_i \leq p_i$) for $i = 1, \ldots, k$ such that $Y \perp E(Y|X)((\alpha_k \otimes \cdots \otimes \alpha_1)^T \text{vec}(X))$, then the column space of $\alpha_i$ is called the $i$th mean dimension folding space. Hence, the column space of $\alpha_k \otimes \cdots \otimes \alpha_1$ is called a dimension folding space for the conditional mean of $Y|X$, or a mean dimension folding space of $Y|X$.

Similar to Definition 1.2, the intersection of all such spaces, if itself is a mean dimension folding space, is called the Central Mean Folding Space for $Y$ on the array-valued $X$. We write this space as $S_{E(Y|X^\otimes k)}$. Thus, similar theory on $S_{E(Y|X^\otimes k)}$ and methods on the estimation of $S_{E(Y|X^\otimes k)}$ can be established straightforwardly from previous sections.

1.7 Discussion

In this chapter, we establish a theory of sufficient dimension folding for the regression mean function with matrix-/array-valued predictors. We illustrate two algorithms for reducing the dimension for matrix-valued predictor along the row and column direction at the same time by using local weighted least squares and linear approximation. We
introduce a modified BIC criterion to estimate the dimensionality of the proposed folding subspaces. We analyze a primary biliary cirrhosis data to show the efficacy of our method, a novel approach for longitudinal data. A bootstrap method is used to evaluate the significance of individual variables. However, variable selection integrating penalty methods such LASSO penalty into the local estimation method is also a possible approach for variable selection. Thus reducing the dimension and variable selection may be carried out simultaneously. Such an idea is currently under investigation.

1.8 Appendix

Proof of Proposition 1.1:

1. (3) ⇒ (1) and (1) ⇒ (2) are immediate.

2. (3) ⇒ (2) is also immediate. Since if \( E(Y|X) \) is a function of \( A^TXB \) then, given \( A^TXB, E(Y|X) \) is a constant and hence independent of any other random variable.

3. For proof of (2) ⇒ (3). By (2) we have

\[
\]

The left hand side is

\[
E\{E[YE(Y|X)|X]|A^TXB\} = E\{[E(Y|X)]^2|A^TXB\}.
\]
The right hand side is

Thus, \( Var[E(Y|X)|A^T XB] = 0 \) which means given \( A^T XB \), \( E(Y|X) \) is a constant. \( E(Y|X) \) is a function of \( A^T XB \).

**Proof of Proposition 1.2:** Let \( A \) and \( B \) be basis matrices of \( S_{E(Y|X)} \) and \( S_{E(Y|X)} \), respectively. Since \( Z \) and \( X \) are one to one correspondent, the following equivalences are valid:

\[
Y \perp E(Y|X)|A^T XB \Leftrightarrow Y \perp E(Y|X)|A^TA_0^T A_0^T XB_0 B_0^{-1} B \\
\Leftrightarrow Y \perp E(Y|Z)|(A_0^T A)^T ZB_0^{-1} B
\]

Therefore, \( S(A_0^T A) = A_0^T S_{E(Y|X)} \) is a left mean dimension folding space for \( E(Y|Z) \) and \( S(B_0^T B) = B_0^T S_{E(Y|X)} \) is a right mean dimension folding space for \( E(Y|Z) \). Consequently,

\[
S_{E(Y|Z)} \subseteq A_0^T S_{E(Y|X)}, \quad S_{E(Y|Z)} \subseteq B_0^T S_{E(Y|X)};
\]

which means \( S_{E(Y|Z)} \subseteq (B_0^T \otimes A_0^T) S_{E(Y|X)} \). By the same argument, \( S_{E(Y|X)} \subseteq A_0 S_{E(Y|Z)} \) and \( S_{E(Y|X)} \subseteq B_0 S_{E(Y|Z)} \) so that \( S_{E(Y|X)} \subseteq (B_0 \otimes A_0) S_{E(Y|Z)} \). Thus \( S_{E(Y|X)} = (B_0 \otimes A_0) S_{E(Y|Z)} \).
Proof of Proposition 1.3: We use the same assumption as Xia, et al. (2002) but on \( \text{vec}(X) \). In addition, we assume that \( \lim_{n \to \infty} \frac{C_n}{nh_{(d,r)}} = 0 \). The proof below follows from Wang and Yin (2008). For simplicity, we assume that \( \text{vec}(X) \) has a compact support over which its density is positive. For any \((d_*, r_*)\), suppose that the semi-orthogonal \( p \times d_* \) and \( q \times r_* \) matrices of \( A_{d_*} \) and \( B_{r_*} \) minimizes \( E \left[ Y - E(Y|A_{d_*}^T X B_{r_*}) \right]^2 \). That is, \( Y_i = E(Y|A_{d_*}^T X_i B_{r_*}) + \epsilon_{d_*,i} \), where \( E(\epsilon_{d_*,i}|A_{d_*}^T X_i B_{r_*}) = 0 \). Suppose the semi-orthogonal \( p \times d_* \) matrix \( \hat{A}_{d_*} \) and semi-orthogonal \( q \times r_* \) matrix \( \hat{B}_{r_*} \) are the sample estimators of \( A_{d_*} \) and \( B_{r_*} \), respectively. And suppose \( \hat{\sigma}^2_{A_{d_*}, B_{r_*}}(A_{d_*}^T X_j \hat{B}_{r_*}) = \sum_{i=1}^n [y_i - \hat{c}_j - \hat{a}_j^T A_{d_*}^T X_i \hat{b}_{r_*}]^2 \),

Using the notation in Section 2 and 3,

\[
\frac{1}{n} \sum_{j=1}^n \hat{\sigma}^2_{A_{d_*}, B_{r_*}}(A_{d_*}^T X_j \hat{B}_{r_*}) - \frac{1}{n} \sum_{j=1}^n \sigma^2_{A_{d_*}, B_{r_*}}(A_{d_*}^T X_j B_{r_*}) + \frac{1}{n} \sum_{j=1}^n \sigma^2_{A_{d_*}, B_{r_*}}(A_{d_*}^T X_j B_{r_*}) - E \left[ Y - E(Y|A_{d_*}^T X B_{r_*}) \right]^2
\]

\[= \frac{1}{n} \sum_{j=1}^n \left[ \sigma^2_{A_{d_*}, B_{r_*}}(A_{d_*}^T X_j \hat{B}_{r_*}) - \sigma^2_{A_{d_*}, B_{r_*}}(A_{d_*}^T X_j B_{r_*}) \right] + o_p(1)\]

\[= \frac{1}{n} \sum_{j=1}^n \left[ \sum_{i} \epsilon_{d_*,i}^2 \omega_{ij} - \sigma^2_{A_{d_*}, B_{r_*}}(A_{d_*}^T X_j B_{r_*}) \right] + o_p(1)\]

\[= o_p(1).\]

The second and the last equations hold by the law of large numbers, and the third equation is based on Lemma 1 of Xia, et al. (2002, the long version) and the law of large
numbers. Note that $E(Y|X) = E(Y|A_d^tXB_r)$.

$$\frac{1}{n} [RSS_{(d_*, r*)} - RSS_{(d, r)}] = E \left[ Y - E(Y|A_d^tXB_{r*}) \right]^2 - E \left[ Y - E(Y|A_d^tXB_r) \right]^2 + o_p(1)$$

$$= E \left[ Y - E(Y|A_d^tXB_{r*}) + E(Y|A_d^tXB_r) - E(Y|A_d^tXB_{r*}) \right]^2$$

$$- E \left[ Y - E(Y|A_d^tXB_{r*}) \right]^2 + o_p(1)$$

$$= 2E \left\{ [Y - E(Y|A_d^tXB_{r*})] [E(Y|A_d^tXB_r) - E(Y|A_d^tXB_{r*})] \right\}$$

$$+ E \left[ E(Y|A_d^tXB_r) - E(Y|A_d^tXB_{r*}) \right]^2 + o_p(1).$$

By the chain rule of conditional expectation, the cross-product is zero. We have

$$\frac{1}{n} [RSS_{(d_*, r*)} - RSS_{(d, r)}] = E \left[ E(Y|A_d^tXB_{r*}) - E(Y|A_d^tXB_r) \right]^2 + o_p(1).$$

Let us consider all possible combinations of $(d_*, r*)$: 1, $d_* > d$ and $r_* > r$; 2, $d_* > d$ and $r_*=r$; 3, $d_* > d$ and $r_* < r$; 4, $d_* = d$ and $r_* > r$; 5, $d_* = d$ and $r_* = r$; 6, $d_* = d$ and $r_* < r$; 7, $d_* < d$ and $r_* > r$; 8, $d_* < d$ and $r_* = r$; 9, $d_* < d$ and $r_* < r$.

For cases, 1, 2, 4 and 5, we have

$$\lim_{n \to \infty} \frac{1}{n} (RSS_{(d_*, r*)} - RSS_{(d, r)}) \geq 0.$$

40
This is true because in such cases, $E(Y|A_d^r XB_r) - E(Y|A^r_d XB_{r*}) = 0$ could happen.

For cases, 3, 6, 7, 8 and 9, we have

$$\lim_{n \to \infty} \frac{1}{n}(RSS_{(d*,r*)} - RSS_{(d,r)}) > 0.$$ 

This is true because in such cases, $E(Y|A_d^r XB_r) - E(Y|A^r_d XB_{r*}) = 0$ never happens; otherwise, it contradicts to the existence of central mean folding subspace. Then,

\[
BIC_{(d*,r*)} - BIC_{(d,r)} = \log \frac{RSS_{(d*,r*)}}{RSS_{(d,r)}} + \frac{C_n}{n h_{(d,r)}^{dr}} [d*r* n^{\frac{4(d*r*-dr)}{4+4dr*(4+dr)}} - dr].
\]  

(1.8.1)

If $\lim_{n \to \infty} \frac{C_n}{n h_{(d,r)}^{dr}} = 0$, then

A: For cases 1, 2, 4 and 5, because $d*r* - dr \geq 0$, the second term in equation (1.8.1) is greater than or equal to 0, while the first term is also greater than or equal to 0. We have $BIC_{(d*,r*)} \geq BIC_{(d,r)}$, when $n$ is large enough.

B: For cases 3, 6, 7, 8 and 9, because if $d*r* - dr \geq 0$, the second term in equation (1.8.1) is greater than or equal to 0; and if $d*r* - dr < 0$, the second term in equation (1.8.1) tends to 0; while the first term is always greater than 0. We have $BIC_{(d*,r*)} > BIC_{(d,r)}$, when $n$ is large enough.

Hence, we complete the proof.

**Proof of Theorem 1.1:** Here we explain how we prove the asymptotic result in Theorem 1.1, assuming that the dimensions of the central right and left mean folding subspace
are $d$ and $r$. Part of the proofs can be referred in Wang and Xia (2008). In particular, we follow the proofs in Yin and Li (2011). In order to be consistent with the symbols we used in the chapter and for notation conciseness, without confusion, we define $B = B \otimes A$, where $A$ and $B$ are the basis matrices for the central left- and right- mean folding subspace respectively. Then $B$ is the orthogonal basis for the central mean folding subspace. And define $B_\ast = B \otimes A_\ast$, $d_j = b_j \otimes a_j$, $X = \text{vec}(X)$, $X_i = \text{vec}(x_i)$ and $x$ is a given value of $X$, where $A_\ast$ and $B_\ast$ are any $p \times d_\ast$ and $q \times r_\ast$ matrices. We work on the proofs in the circumstance of $B \otimes A$ and $\text{vec}(X)$. Because, once we have an estimate $\hat{B}$ of $B$ and $\hat{B}$ is Kronecker product structural between $\hat{B}$ and $\hat{A}$, then we can iteratively estimate $\hat{A}$ and $\hat{B}$ by the matrix decomposition method introduced in Section 3.1. We can prove the asymptotic result following Yin and Li (2011) because

In the folded-MAVE method, we solve the quadratic minimization:

$$
\sum_{j=1}^{n} \sum_{i=1}^{n} \rho_j [y_i - c_j - a_j^T A^T (x_i - x_j) B b_j]^2 w_{ij},
$$

(1.8.2)

over $(c_j, a_j, b_j, A, B) \in \mathbb{R}^1 \times \mathbb{R}^d \times \mathbb{R}^r \times \mathbb{R}^p \times \mathbb{R}^q$, subject to $b_j^T b_j = 1$, $A^T A = I_d$, $B^T B = I_r$, for $i = 1, \ldots, n$ and $j = 1, \ldots, n$. Note that (1.8.2) is equivalent to

$$
\sum_{j=1}^{n} \sum_{i=1}^{n} \rho_j [y_i - c_j - (b_j \otimes a_j)^T (B \otimes A)^T \text{vec}(x_i - x_j)]^2 w_{ij}.
$$

(1.8.3)
Under our definitions that $B = B \otimes A$, $d_j = b_j \otimes a_j$, $X = \text{vec}(X)$, $X_i = \text{vec}(x_i)$ and $X_{ij} = \text{vec}(x_i - x_j)$, (1.8.3) transforms to

$$\sum_{j=1}^{n} \sum_{i=1}^{n} \rho_j [y_i - c_j - d_j^T B^T X_{ij}]^2 w_{ij}. \tag{1.8.4}$$

Note that the formulation (1.8.4) is exactly what Yin and Li (2011) had for the objective function, if one sets $f(y_i) = y_i$ and $m = 1$. In such a case, when the central mean subspace of $\text{vec}(X)$ is the same as that of the folding subspace, estimating $B$ directly by the weighted least squares method will suffice. Hence, the asymptotic results follow immediately. However, when the central mean subspace of $\text{vec}(X)$ is not the same as that of the folding subspace, estimating $B$ directly by the weighted least squares method will return a basis matrix for other subspaces rather than the central mean folding subspace, usually a subspace of folding space if dimensions are assumed correctly. To prevent the latter case, we notice that the Kronecker product structure of $B$ can be recovered by using the local iterative methods we have proposed. Thus, the final estimate, $\hat{B} = \hat{B} \otimes \hat{A}$, is then the weighted least squares solution of (1.8.4) with such a structure. Therefore, we can prove the asymptotic result exactly following Yin and Li’s (2011) procedure.

Chapter 2

Dimension folding for a functional of conditional distribution of matrix- or array-valued objects

2.1 Introduction

Sufficient dimension folding (Li, Kim and Altman, 2010; Chapter 1) is a technology for reducing the dimensions of matrix-/array-valued objects as much as possible while preserving the underlying structure interpretation of the predictor. Sufficient dimension folding subspace (Li, Kim and Altman, 2010) focuses on reducing the dimensions of the matrix-/array-valued predictor (\(X\)) as it appears in the conditional distribution of a univariate response \(Y\) given \(X\). Li, Kim and Altman (2010) proposed the concept...
of Kronecker envelope based on which they suggested folded-SIR, folded-SAVE and folded-DR three estimation methods for the CFS. Sufficient mean dimension folding subspace (Chapter 1) is only interested in the conditional mean of $Y$ given $X$ instead of the full conditional distribution itself. To estimate the CMFS, Xue and Yin (2012) constructed two local estimation methods: folded-OPG and folded-MAVE. However, if the assumption of homoscedasticity is violated or outliers present, we need to consider the robust regression relationship between a univariate response $Y$ and a matrix-/array-valued predictor $X$.

For a vector-valued predictor, there is a huge literature of research on robustness. For instance, trimmed mean estimator, M-estimator and Huber estimator (Huber, 1964). Quantile regression is an important robust statistics (Koenker, 2005; Wu, Yu and Yu, 2010; Yu and Jones, 1998; Zou and Yuan, 2008; Kai, Li and Zou, 2010). However, to our knowledge, a robust approach of dimension folding for matrix-/array-valued predictor has not been studied by any researcher yet. In this chapter, we reformulate dimension folding and characterize specific aspects of the conditional distribution of $Y$ given a matrix-/array-valued predictor by adopting a general functional of the conditional distribution. By performing dimension folding in reference to a functional, the relation between $Y$ and the predictor reflected in that functional is preserved. For a general functional $T$, we propose a concept of central $T$ dimension folding subspace (CTFS). The CFS and CMFS can be synthesized as two special cases of the CTFS. Besides, we introduce several other special cases of the CTFS, such as the central variance dimension folding subspace (CVFS), central $k$–th moment dimension folding subspace (CKMFS)
and central quantile dimension folding subspace (CQFS). Further, we establish a class of estimation methods for dimension folding on robust estimators. We focus on estimating the CQFS as a special example to illustrate the proposed methods. A special case when the predictor is vector-valued can be found in Yin and Li (2012).

The rest of this chapter is organized as follows. In Section 2.2, we define the central folding space for a general functional of conditional distribution of matrix objects and investigate its properties as well as several special cases. In Section 2.3, we introduce a general approach to estimate the CQFS. We consider estimating the CQFS as an illustration on how to apply the proposed algorithms to estimate a certain aspect of the functional in Section 2.4. Simulations on estimating CQFS and application are included in Section 2.5 and Section 2.6 respectively, followed by a brief extension to array-valued predictors in Section 2.7. A short discussion is provided in Section 2.8.

2.2 Central folding space for a functional of conditional distribution of matrix object

Without confusion, we will let $\mathcal{S}(A)$ denote a space spanned by the columns of a matrix $A$. We use $\mathcal{S}_{(\cdot)}$ to denote a dimension-folding subspace, where the subscript indicates what response and predictors are involved, and whether the whole conditional distribution or only the conditional mean, variance or quantiles is of interest. And we use
$P_A$ to denote the orthogonal projection onto $\mathcal{S}(A)$, that is, $P_A = A(A^TA)^+A$, where "$\dagger$" denotes the Moore-Penrose inversion.

Throughout the chapter, we assume that $X$ is a $p \times q$-dimensional random matrix and $Y$ is a random variable and their sample points are $(x_i, y_i), i = 1, \ldots, n$, where $n$ is the sample size. We assume that the support $\Omega$ of $(X, Y)$ is the Cartesian product $\Omega_X \times \Omega_Y$, where $\Omega_X \subseteq \mathbb{R}^{p \times q}$ is the support of $X$ and $\Omega_Y \subseteq \mathbb{R}^1$ is the support of $Y$. Let $F$ be the joint distribution of $(X, Y)$, and $F_{Y|X}$ be the conditional distribution of $Y|X$. For each fixed $x \in \Omega_X$, $F_{Y|X}(\cdot|x)$ is a probability measure on $\Omega_Y$ and for each measurable set $A_Y \subseteq \Omega_Y$, $F_{Y|X}(A_Y|x)$ is a measurable function of $x$. Then the set $\{F_{Y|X}(\cdot|x) : x \in \Omega_X\}$ defines a family of probability measures on $\Omega_Y$. Let $T$ be a functional defined on this family:

$$T : \{F_{Y|X}(\cdot|x) : x \in \Omega_X\} \rightarrow \mathbb{R}^1.$$ 

The functional $T$ can be viewed as a parameter associated with the conditional distribution $F_{Y|X}$. From here on, we will abbreviate this functional $T(F_{Y|X}(\cdot|x))$ as $T(x)$. The functional $T$, when considered as a mapping $F_{Y|X}(\cdot|x) \rightarrow T(F_{Y|X}(\cdot|x))$, is a functional of conditional distribution, when considered as a mapping $x \rightarrow T(F_{Y|X}(\cdot|x))$, is simply a function of $x$.

In the sufficient dimension folding, one considers finding matrices $A \in \mathbb{R}^{p \times d}$ and $B \in \mathbb{R}^{q \times r}$ such that $d$ and $r$ are as small as possible and $F_{Y|X}$ depends on $X$ only through $A^T XB$, while preserving the matrix structure of $X$ (Li, Kim and Altman, 2010). Spaces spanned by the columns of $A$ and $B$ are called the left- and right- dimension folding sub-
space, respectively. Let $S_{Y|\circ X}$ or $S_{Y|X^\circ}$ be the intersection of all left- or right- dimension folding subspaces for $Y|X$. The subspace $S_{Y|X^\circ} \otimes S_{Y|\circ X}$ is defined as the central dimension folding subspace (CFS) denoted by $S_{Y|\circ X^\circ}$, where “$\otimes$” is the Kronecker product. In Chapter 1, we introduced the central mean dimension folding subspace (CMFS), which particularly focuses on the conditional mean function of $F_{Y|X}$. We considered finding matrices $A \in \mathbb{R}^{p \times d}$ and $B \in \mathbb{R}^{q \times r}$, $d \leq p$ and $r \leq q$, such that $Y \indep E(Y|X) A^T X B$, where “$\indep$” stands for conditional independent. The subspaces $S(A)$ and $S(B)$ are called a left- or right- mean dimension folding subspace, respectively. If the intersection of all left- or right- mean folding subspace is itself a left- or right- mean folding subspace of $E(Y|X)$, we denoted the intersection subspace by $S_{E(Y|\circ X)}$ or $S_{E(Y|X^\circ)}$. We also defined $S_{E(Y|\circ X)}$ and $S_{E(Y|X^\circ)}$ as the central left- and right- mean dimension folding subspace, respectively. Then $S_{E(Y|X^\circ)} \otimes S_{E(Y|\circ X)}$ is the sufficient central mean dimension folding subspace.

CFS and CMFS are interested in a certain parameter, as described by the above functional $T$, associate with $F_{Y|X}$ and others not related to this functional are analogous to the nuisance parameter in a classical setting. Targeting on different dimension folding subspaces, we only need to fold the dimensions of predictors with respect to some specific parameter in the associated functional $T$ (Li, Kim and Altman, 2010; Xue and Yin, 2012).

In this chapter, our goal is to derive a comprehensive method to estimate the dimension folding subspace associated with a general functional $T$. We define the dimension folding
spaces with respect to a functional $T$ of the conditional distribution when $X$ is a random matrix as:

**Definition 2.1.** If there are matrices $A \in \mathbb{R}^{p \times d}$ and $B \in \mathbb{R}^{q \times r}$ ($d \leq p, r \leq q$) such that $T(x)$ depends on $x$ only through $A'XB$, that is $T(x) = T(x^*)$ whenever $A'XB = A'X'B$, then the column space of $A$ or $B$ are called a left- or right- dimension folding space for the functional $T$, or $T$-left- or right- dimension folding space. Let $S_{Y|oX}(T)$ or $S_{Y|X^o}(T)$ be the intersection of all $T$-left- or right- dimension folding space and itself is a left- or right- $T$ dimension folding space. Then $S_{Y|oX}(T)$ and $S_{Y|X^o}(T)$ are defined as the central left- and right- $T$ dimension folding space. The space $S_{Y|X^o}(T) \otimes S_{Y|oX}(T)$ is called the central dimension folding space for functional $T$, or the central $T$ dimension folding subspace (CTFS) and is written as $S_{Y|oX^o}(T)$.

That the intersection of two $T$-dimension folding spaces is again a $T$-dimension folding space can be established under very mild conditions using the same argument recently made by Yin, Li and Cook (2008); see also Proposition 6.4 of Cook (1998) and Theorems 1 and 2 of Li, Kim and Altman (2010). We state it here without proof. The following corollary 2.1 states the condition when the CTFS exists and is the unique minimal $T$-dimension folding space. We assume that this condition holds throughout the article and denote the dimensionality of $S_{Y|oX}(T)$ or $S_{Y|X^o}(T)$ by $d$ or $r$.

**Corollary 2.1.** Suppose that $A_i, B_i, i = 1, 2$, are $p \times d_i, q \times r_i$ with $d_i \leq p$ and $r_i \leq q$ such that $S(B_1 \otimes A_1)$ and $S(B_2 \otimes A_2)$ are both $T$-dimension folding subspaces. Let $A_3, B_3$ be $p \times d_3$ and $q \times r_3$ dimensional matrices whose columns span the intersection of
\[ S(B_1 \otimes A_1) \text{ and } S(B_2 \otimes A_2). \] Suppose, in addition, that for each \( \mu \in \mathbb{R}^{d_1 \times r_3} \) such that \( A_3^T x B_3 = \mu \) for some \( x \in \Omega_X \), the set

\[
\{(A_1^T x B_1, A_2^T x B_2) : A_3^T x B_3 = \mu, x \in \Omega_X\}
\] (2.2.1)

is an M-set in \( \mathbb{R}^{d_1 \times r_1} \times \mathbb{R}^{d_2 \times r_2} \) as defined by Yin, Li and Cook (2008). Then \( S(B_1 \otimes A_1) \cap S(B_2 \otimes A_2) \) is also a T dimension folding subspace.

Lemma 2.1 below whose proof is detailed in the Appendix indicates that it is the space spanned by the columns of \( A \) or \( B \) that we should care about rather than the specific value of the matrices. The definition of central T folding subspace involves using the point 3, but based on the equivalences of points 1 and 2, it is the subspace that uniquely determines the sufficient dimensions.

**Lemma 2.1.** Suppose matrices \( A \in \mathbb{R}^{p \times d} \) and \( B \in \mathbb{R}^{q \times r} \) \((d \leq p, r \leq q)\) and the column vectors of each matrix are linearly independent, and let \( f(t) \) be a function of \( t \in \mathbb{R}^{p \times q} \). For any \( \Sigma_A \in \mathbb{R}^{p \times p}_+ \) and \( \Sigma_B \in \mathbb{R}^{q \times q}_+ \), let \( P(\Sigma_A) = A(A^T \Sigma_A A)^{-1} A^T \Sigma_A \) and \( P(\Sigma_B) = B(B^T \Sigma_B B)^{-1} B^T \Sigma_B \) be the projection onto \( S(A) \) and \( S(B) \) respectively with respect to inner product \( \langle a, b \rangle = a^T \Sigma b \). Then the following statements are equivalent:

1. there are \( \Sigma_A \in \mathbb{R}^{p \times p}_+ \) and \( \Sigma_B \in \mathbb{R}^{q \times q}_+ \) such that \( f(t) = f(P^T(\Sigma_A)tP(\Sigma_B)) \) for all \( t \);

2. for every \( \Sigma_A \in \mathbb{R}^{p \times p}_+ \) and \( \Sigma_B \in \mathbb{R}^{q \times q}_+ \), \( f(t) = f(P^T(\Sigma_A)tP(\Sigma_B)) \) for all \( t \);

3. \( f(t) \) depends on \( t \) only through \( A^T t B \); that is, whenever \( A^T t_1 B = A^T t_2 B \), we have \( f(t_1) = f(t_2) \).
Like the CMFS, under affine linear transformation, the CTFS is invariant. We delay the proof of the following proposition to the Appendix as well.

**Proposition 2.1.** Let \( Z = A^T X B \) where \( A \) and \( B \) are full rank, \( p \times p \) and \( q \times q \) matrices respectively. Then \( S_{Y|\circ Z_0}(T) = (B^\top \otimes A^\top) S_{Y|\circ X_0}(T) \).

The formulation of CTFS accommodates CFS and CMFS as its special cases, which aims at estimating a certain aspect of the conditional distribution. We can link CFS and CMFS to CTFS as in the following Example 2.1 and 2.2. Also, the formulation of CTFS suggests some other examples as follows.

**Example 2.1.** For an \( a \in \Omega_Y \), let \( T_a \) be defined as the evaluation of \( F_{Y|X}(\cdot|\mathbf{x}) \) at \( y = a \). That is, \( T_a \) assigns to each function \( F_{Y|X}(\cdot|\mathbf{x}) \) the number \( F_{Y|X}(a|\mathbf{x}) \). Then the union of all \( S_{Y|\circ X_0}(T_a) \) reduces to the Central Dimension Folding Space (Li, Kim and Altman, 2010).

**Example 2.2.** If \( T(\mathbf{x}) = \int y dF_{Y|X}(y|\mathbf{x}) \), then \( T(\mathbf{x}) \) is the conditional mean \( E(Y|\mathbf{X} = \mathbf{x}) \). Thus the CTFS reduces to the Central Mean Dimension Folding Space (Chapter 1).

**Example 2.3.** If \( T(\mathbf{x}) = \int y^2 dF_{Y|X}(y|\mathbf{x}) - (\int y dF_{Y|X}(y|\mathbf{x}))^2 \), then \( T(\mathbf{x}) \) is the conditional variance, \( \text{Var}(Y|\mathbf{X} = \mathbf{x}) \), given a matrix predictor \( \mathbf{X} \). We define this folding subspace as the central variance dimension folding subspace (CVFS) denoted by \( S_{V(|\circ X_0)} \).

**Example 2.4.** If \( T(\mathbf{x}) = [M^{(1)}(Y|\mathbf{X}), M^{(2)}(Y|\mathbf{X}), \ldots, M^{(k)}(Y|\mathbf{X})] \), where \( M^{(k)}(Y|\mathbf{X}) = \int[y - \int y dF_{Y|X}(y|\mathbf{x})]^{k} dF_{Y|X}(y|\mathbf{x}) \) for \( k \geq 2 \) and \( M^{(1)}(Y|\mathbf{X}) = \int y dF_{Y|X}(y|\mathbf{x}) \), then we define this special example of the CTFS as the central \( k \)-th moment dimension folding subspace (CKMFS).
The concept of linear functionals, the intrinsically linear functionals and the minimization functionals discussed in Yin and Li (2012) can be easily extended to the domain of dimension folding by replacing the vector-valued predictor $X$ by the matrix-/array-valued predictor $X$. Their properties also remain the same as for vector predictors. Based on the definition of minimization functionals for the matrix predictor $X$, we illustrate the central quantile folding subspace as follows.

**Example 2.5.** Let $\rho(\theta, y)$ be a function of $\theta$ and $y$. Suppose, for each $x \in \Omega_X$, the following function of $\theta$

$$
\int \rho(\theta, y) dF_Y|X(y|x)
$$

(2.2.2)

has a unique minimum. Then the functional $T$ defined as the minimizer of the above function is a minimization functional, or an $M$-functional. Suppose that $0 < \tau < 1$ and $I(\cdot)$ is the indicator function and let

$$
\rho_\tau(\theta, y) = \tau I(y - \theta > 0)(y - \theta) + (\tau - 1)I(y - \theta \leq 0)(y - \theta)
$$

$$
= (y - \theta)[\tau - I(y - \theta \leq 0)].
$$

Then the CTFS of this type is the central quantile folding space (CQFS) denoted by $S_{Q,\tau}(Y|X)$. If $\tau = 0.5$ or $\rho(\theta, y) = |y - \theta|$, $S_{Q_{0.5}}(Y|X)$ is the central median folding subspace, denoted by $S_{M(Y|0X_0)}$.

Next, we propose a class of methods that can be used to estimate the central $T$ dimension folding subspace for matrix predictors. We also establish a new theory for local
central folding space for a functional of conditional distribution, from which we provide a connection between local theory of sufficient dimension folding and sufficient dimension folding. In the population level, local method can be used as a class of estimation method for sufficient dimension folding. As a special case, we use the proposed method to estimate the CQFS for the consideration of robust regression.

2.3 General approach to estimate the CTFS

2.3.1 Measurement of accuracy

To evaluate the accuracy of estimates we use the matrix norm

\[ \Delta(B \otimes A, \hat{B} \otimes \hat{A}) = \| P_{B \otimes A} - P_{\hat{B} \otimes \hat{A}} \| \]

(Li, Zha and Chiaromonte, 2005). Here, we use the Frobenius norm and denote it as \( \Delta_f \). A small value of \( \Delta_f \) means the two spaces are closed to each other. To understand how accurate the estimates are, we adopt the benchmark distance in Li, Wen and Zhu (2008). Benchmark distance measures the discrepancy between two spaces that are not related at all. Li, Wen and Zhu (2008) defined the benchmark distance as follows. Let \( \alpha \) and \( \beta \) be \( s \times t \) random matrices whose entries are independent standard normal distributed random variables and satisfy \( \alpha \perp \beta \). Let \( P_{\alpha} \) and \( P_{\beta} \) be the projections onto the column space spanned by \( \alpha \) and \( \beta \) respectively. Then \( E(||P_{\alpha} - P_{\beta}||) \) is the benchmark distance.
determined only by the value of $s$ and $t$. We estimate the benchmark distance by running 10,000 simulations and denote it by $\Delta_B$.

### 2.3.2 Local central folding space for a functional of conditional distribution

Here, we define a local central folding space for a functional of conditional distribution. We replace $\Omega$ by a local support $\Delta$, where $\Delta \subseteq \Omega$. For simplicity, $\Delta = \Delta_x \times \Delta_y$, where $\Delta_x \subseteq \Omega_X$ and $\Delta_y \subseteq \Omega_Y$. For convenience, we denote a local CTFS as $S_{Y|\circlearrowleft x_0}(T_{\Delta})$, where $T_{\Delta}$ is the same as $T$ but with $(X, Y) \in \Delta$. Thus if $\Delta = \Omega$, then $S_{Y|\circlearrowleft x_0}(T_{\Delta}) = S_{Y|\circlearrowleft x_0}(T)$.

We use $\text{vec}(\cdot)$ as the operator that stacks a matrix into a vector, column by column. We also use $\text{mat}_t(\cdot)$ to define the inverse operation of $\text{vec}(\cdot)$, which transforms a vector to a matrix with $t$ rows. For example, for any matrix $M \in \mathbb{R}^{t \times s}$ and $M = (m_1, \ldots, m_s)$, then $\text{vec}(M) = (m_1^T, \ldots, m_s^T)^T$. Suppose $m = \text{vec}(M)$ be a vector in $\mathbb{R}^{ts}$, where $ts = t \times s$, then $\text{mat}_t(m) = M$. In short, $\text{mat}_t[\text{vec}(M)] = M$, and $\text{vec}[\text{mat}_t(m)] = m$.

Let $A$ and $B$ be the $p \times d$ and $q \times r$ basis matrices for $S_{Y|\circlearrowleft x}(T_{\Delta})$ and $S_{Y|\circlearrowleft x_0}(T_{\Delta})$, respectively. Then $B \otimes A$ is a basis matrix of $S_{Y|\circlearrowleft x_0}(T_{\Delta})$. Suppose $s = A^T XB$, then the key fact underlying the subsequent development is

$$
\frac{\partial T_{\Delta}(x)}{\partial \text{vec}(x)} = \frac{\partial \text{vec}(s)^T}{\partial \text{vec}(x)} \cdot \frac{\partial T_{\Delta}(s)}{\partial \text{vec}(s)} = (B \otimes A) \cdot \frac{\partial T_{\Delta}(s)}{\partial \text{vec}(s)},
$$

(2.3.1)
\[ \text{mat}_p[\partial T_\Delta(x)/\partial \text{vec}(x)] = A_{\text{mat}}[\partial T_\Delta(s)/\partial \text{vec}(s)]B^T \]  

(2.3.2)

(Schott 1997).

Equation (2.3.1) implies \( \partial T_\Delta(x)/\partial \text{vec}(x) \in S_{Y|oX_o}(T_\Delta) \). We have the following two propositions and their proofs are delayed to the Appendix as well.

**Proposition 2.2.** \( S\{\partial T_\Delta(x)/\partial \text{vec}(x) : (x, y) \in \Delta \} = S_{Y|oX_o}(T_\Delta) \)

Proposition 2.2 implies that the collection of \( \partial T_\Delta(x)/\partial \text{vec}(x) \) for all \((x, y) \in \Delta\) spans the local CTFS, regardless of the form of the functional \( T_\Delta \). If \( \Delta = \Omega \), then it characterizes the CTFS. One can develop estimation methods based on Proposition 2.2.

For instance, let \( w(x, y) > 0 \) be a weight function for all \((x, y) \in \Delta\), and define
\[ \eta_\Delta = E\left[w(x, y) \frac{\partial T_\Delta(x)}{\partial \text{vec}(x)} \frac{\partial T_\Delta(x)}{\partial \text{vec}(x)^T}\right]. \]

Then \( S(\eta_\Delta) = S_{Y|oX_o}(T_\Delta) \). One possible choice is \( w(x, y) \equiv 1 \).

The next proposition indicates that it is enough to estimate the specific CTFS based on a local support of \( X \) only. Based on the following proposition, we propose an approach to estimate the CTFS through the \( M \)-functionals and the respective local CTFS.

**Proposition 2.3.** For any \( \Delta \subseteq \Omega \), it is always true that \( S_{Y|oX_o}(T_\Delta) \subseteq S_{Y|oX_o}(T) \) and further, \( S\{S_{Y|oX_o}(T_\Delta), \Delta = \Delta_x \times \Omega_y \ for \ all \ x \in \Omega_X \} = S_{Y|oX_o}(T) \).
2.3.3 Estimation methods of CTFS

An initial estimator

In this section, we assume $d$ and $r$, the dimensions of $S_{Y|X}(T)$ and $S_{Y|X^c}(T)$, are known.

By using the local linear smoothing (Fan and Gijbels, 1996), for each $j = 1, \ldots, n$, at sample point $x_j$ we minimize the following objective function over $a_j \in \mathbb{R}^p$, $b_j \in \mathbb{R}^q$ and $c_j \in \mathbb{R}^1$ subject to $b_j^T b_j = 1$. The general objective function is

$$
\frac{1}{n} \sum_{i=1}^{n} \rho(y_i, c_j + a_j^T x_{ij} b_j) w_{ij},
$$

where $x_{ij} = x_i - x_j$ and $w_{ij} \geq 0$ is the kernel weight centered at $x_{ij}$ with $\sum_{i=1}^{n} w_{ij} = 1$.

We use the usual kernel weight

$$
w_{ij}(h) = K_h(\text{vec}(x_{ij}))/\sum_{j=1}^{n} K_h(\text{vec}(x_{ij})),
$$

where $K_h(\cdot)$ is the chosen kernel function with the bandwidth $h > 0$. We set $h = n^{-1/(p+q+4)} \times \sqrt{p \times q}$ (Silverman, 1986).

In order to estimate $a_j$, $b_j$ and $c_j$, we propose the following iterative algorithm:

1. Generate the initial values of $a_j \in \mathbb{R}^p$ from a sample of $N(0,1)$ random variables.

2. For each $j = 1, \ldots, n$, given a fixed $a_j \in \mathbb{R}^p$, minimize (2.3.3) over $c_j \in \mathbb{R}^1$, $b_j \in \mathbb{R}^q$ subject to $b_j^T b_j = 1$. Suppose the minimizers are $\hat{c}_j$ and $\hat{b}_j$. 

62
3. For each $j = 1, \ldots, n$, given the estimate $\hat{c}_j$ and $\hat{b}_j$ from Step 1, minimize (2.3.3) over $a_j \in \mathbb{R}^p$. And suppose the estimate is $\hat{a}_j$.

4. Let $\hat{A}(k), \hat{B}(k)$ be the first $d$ or $r$ leading eigenvectors of

$$
\hat{\Sigma}_1 = \frac{1}{n} \sum_{j=1}^{n} \hat{a}_j \hat{a}_j^T \quad \text{or} \quad \hat{\Sigma}_2 = \frac{1}{n} \sum_{j=1}^{n} \hat{b}_j \hat{b}_j^T
$$

obtained in the $k$-th iteration. Let $\eta(k) = \hat{B}(k) \otimes \hat{A}_0(k)$, $\eta_0(k-1) = \hat{B}_{(k-1)} \otimes \hat{A}_{(k-1)}$, where $\hat{A}_{(k-1)}$ and $\hat{B}_{(k-1)}$ are the estimators of $A$ and $B$ in the $(k-1)$-th iteration. If $||\eta(k) \eta(k)^T - \eta(k-1) \eta(k-1)^T||$ is smaller than some pre-specified tolerance value, such as $10^{-6}$, stop the iteration and set $A = \hat{A}(k), B = \hat{B}(k)$ as the estimates of $S_{Y|oX}(T)$ and $S_{Y|X_0}(T)$ respectively; otherwise, set $k := k + 1$ and go to Step 2.

**The refined estimator**

In order to attain more accurate estimates of $A$ and $B$, we can further refine the $A_{opg}$ and $B_{opg}$, the basis matrix for $S_{Y|oX}(T)$ and $S_{Y|X_0}(T)$ obtained by the previous procedure. We suggest the following algorithm: given $A(k)$ and $B(k)$, the estimates of $A$ and $B$ in the $k$-th iteration, we can iteratively estimate $A(k+1)$ and $B(k+1)$ in the next iteration by minimizing the global loss function:

$$
n^{-2} \sum_{j=1}^{n} \sum_{i=1}^{n} \rho(y_i, c_j + a_j^T A^T x_{ij} B b_j) K_{h(d,r)} \left( \text{vec}(A(k)^T x_{ij} B(k)) \right),
$$

(2.3.4)
subject to $c_j \in \mathbb{R}^1$, $a_j \in \mathbb{R}^d$, $b_j \in \mathbb{R}^r$ with $b_j^Tb_j = 1$, $A \in \mathbb{R}^{p \times d}$ with $A^T A = I_d$ and $B \in \mathbb{R}^{q \times r}$ with $B^T B = I_r$. We will use the refined kernel weights and summarize the algorithm as:

1. Generate the initial values of $a_j \in \mathbb{R}^d$ from a sample of $N(0,1)$ random variables.
   Set the initial estimates of $A$ and $B$ as $A_{opg}$ and $B_{opg}$.

2. In the $k$-th iteration, for a fixed $a_{j(k-1)}$, $A_{(k-1)}$, and $B_{(k-1)}$, calculate $\hat{b}_{j(k)}$ and $\hat{c}_{j(k)}$, the estimates of $b_j$ and $c_j$, as the minimizers of

\[
\sum_{i=1}^{n} \rho(y_i, c_j + a_{j(k-1)}^T A_{(k-1)}^T x_{ij} B_{(k-1)} b_j) K_{h(d,r)}(\text{vec}(A_{(k-1)}^T x_{ij} B_{(k-1)})).
\]

3. In the $k$-th iteration, given the fixed $c_{j(k)}$, $b_{j(k)}$, $A_{(k-1)}$, and $B_{(k-1)}$, $\hat{a}_{j(k)}$, the estimate of $a_{j(k)}$, is the minimizer of

\[
\sum_{i=1}^{n} \rho(y_i, c_{j(k)} + a_{j(k)}^T A_{(k-1)}^T x_{ij} B_{(k-1)} b_{j(k)}) K_{h(d,r)}(\text{vec}(A_{(k-1)}^T x_{ij} B_{(k-1)})).
\]

4. Given the fixed $a_{j(k)}$, $b_{j(k)}$, $c_{j(k)}$ and $B_{(k-1)}$, minimizing the objective function below over $A$ with $A^T A = I_d$, in the $k$-th iteration.

\[
n^{-2} \sum_{j=1}^{n} \sum_{i=1}^{n} \rho(y_i, c_{j(k)} + a_{j(k)}^T x_{ij} B_{(k-1)} b_{j(k)}) K_{h(d,r)}(\text{vec}(A_{(k-1)}^T x_{ij} B_{(k-1)})),
\]

to obtain $\hat{A}_{(k)}$. 

64
5. Given the \(a_{j(k)}, b_{j(k)}, c_{j(k)}\) and \(A(k)\), minimize the objective function:

\[
n^{-2} \sum_{j=1}^{n} \sum_{i=1}^{n} \rho(y_i, c_{j(k)} + a_{j(k)}^T A_{(k)}^T x_{ij} B b_{j(k)}) K_{h_{(d,r)}}(\text{vec}(A_{(k)}^T x_{ij} B (B_{(k)}))) ,
\]

over \(B\) subject to \(B^T B = I_r\), to obtain \(\hat{B}_{(k)}\).

6. Check the convergence. Let \(\eta_{(k)} = B_{(k)} \otimes A_{(k)}, \eta_{(k-1)} = B_{(k-1)} \otimes A_{(k-1)}\). If

\[
\|\eta_{(k)} \eta_{(k)}^T - \eta_{(k-1)} \eta_{(k-1)}^T \| \text{ is smaller than some pre-specified tolerance value, such as } 10^{-6}, \text{ stop the iteration and set } \hat{A} = A_{(k)}, \hat{B} = B_{(k)}; \text{ Otherwise, set } k := k + 1 \text{ and go to Step 2.}
\]

### 2.3.4 Estimation of the CTFS dimension

We can adopt the modified BIC criterion introduced in Chapter 1 to estimate \(d\) and \(r\). However, \(RSS_{(d_*, r_*)}\), the residual sum of squares when \(d = d_*\) and \(r = r_*\) changes to

\[
\sum_{j=1}^{n} \sum_{i=1}^{n} \rho(y_i, \hat{c}_j + \hat{a}_j^T \hat{A}_{ij} \hat{B} b_{j(k)}) K_{h_{(d_*, r_*)}}(\text{vec}(\hat{A}_{ij} \hat{B})). \tag{2.3.5}
\]

In this chapter, we also set \(C_n = (0.5 \log(n) + 0.1n^{1/3})/2\) (Zhu, Miao and Peng, 2006). We do not consider the asymptotic properties for the quantile dimension folding because there exist no closed form formulas with explicit solutions for the quantile regression. Kong and Xia (2012) and Wu, Yu and Yu (2010) investigated the asymptotic properties of the quantile estimators for single index model. However, for multiple index model, investigating the asymptotic properties poses a challenge.
2.4 Estimation of the CQFS

In what follows, we work on estimation of the CQFS, a special case of the CTFS. From the aspect of dimension folding, the absolute loss function $\rho(\cdot)$ in the objective functions (2.3.3) and (2.3.4) will be $u[\tau - I(u < 0)]$, where $u$ is the prediction error and $0 < \tau < 1$ is the $\tau$-th quantile we are interested in. The selection of the bandwidth for estimating the CQFS can be done as in Yu and Jones (1998). Yu and Jones (1998) suggested the relationship between the optimal bandwidth for conditional mean regression and that for conditional quantile as:

$$h_{\tau} = h_{\text{mean}}\left[\tau(1 - \tau)/\phi(\Phi^1(\tau))\right]^{1/5},$$

where functions $\phi(\cdot)$ and $\Phi(\cdot)$ are the probability density function and the cumulative distribution function of the standard normal distribution respectively. The bandwidth $h_{\tau}$ is the bandwidth for single-index quantile regression and $h_{\text{mean}}$ is the optimal bandwidth for local linear smoothing estimator in single-index mean regression. For $h_{\text{mean}}$, we can choose $h_{\text{mean}} = g(d, r)n^{-1/(dr+4)}$ (Silverman, 1986), where $g(d, r) = \frac{4}{dr+2}1/(4+dr)$ and $dr$ is the dimension of the refined kernel function. The bandwidth $h_{\tau}$ is a function of $\tau$, $d$ and $r$. In our simulations, we consider $\tau = 0.5$ or $\tau = 0.75$ thus the coefficient $[\tau(1 - \tau)/\phi(\Phi^1(\tau))]^{1/5}$ equals to 0.9107643 and 0.8998619 respectively. And $g(d, r)$ equals to 1.059224, 1 or 0.9505789. Since the $g(d, r)[\tau(1 - \tau)/\phi(\Phi^1(\tau))]^{1/5}$ ranges from 0.8553906 to 0.9647034, we can simply set $h_{d,r} = n^{-1/(d \times r+4)}$. 

66
2.5 Numerical Study

In the following models, we assume the error $\epsilon$ is independent of the predictor matrix $X$. For $X$, $\text{vec}(X) \sim N_{pq}(0, \Sigma_{\text{vec}(X)})$ and $\Sigma_{\text{vec}(X)}$ is a $pq \times pq$ positive definite matrix with $(j_1, j_2)$th entry $0.5^{|j_1-j_2|}$. And suppose $e_1 = (1, 0, 0, 0)^T$, $e_2 = (0, 1, 0, 0)^T$ and $e_3 = (0, 0, 1, 0)^T$. Each simulation is run 100 replications. We report accuracy of estimating CQFS as: mean $\pm$ standard deviation, and accuracy of dimensions estimation in percentages. And we use the same standardization approach for $X$.

Example 2.6. We consider the following nonlinear model with $p = q = 5$, $\beta_1 = (1, 1, 0, 0, 0)^T$ and $\beta_2 = (0, 1, 0, 0, 0)^T$.

$$Y = (\beta_1^T X \beta_2)^4 + .2\epsilon.$$

This model will produce extreme values around the origin. And $S_{M(Y|\{oX\o\})} = S_{Q_r(Y|\{oX\o\})} = S(\beta_2) \otimes S(\beta_1)$ with $d = 1, r = 1$. We consider three distributions for $\epsilon$: standard normal, and the heavy tailed distribution, $t_1$, $t$-distribution with one-degree of freedom. Since the expectation of $t_1$ and the variance of $t_2$ are not defined, we also consider $t_3$, $t$-distribution with three-degree of freedom for the error term $\epsilon$. The respective results for $\epsilon \sim t_1$ and $\epsilon \sim t_3$ are reported in the parenthesis and square bracket. We apply our method with $\tau = 0.5$ and $\tau = 0.75$ and sample size of 200, 300, 400 and 600. The benchmark distance is $1.384$. 

From Table 2.1, we can see the accuracy increases as sample size increases and the accuracy decreases when error distribution switches from normal distribution to $t_3$ and from $t_3$ to $t_1$ for all models. Since relatively $\tau = 0.75$ calculates extreme tails, the accuracy decreases from $\tau = 0.5$ to $\tau = 0.75$. The estimated percentage for correctly identifying dimensionality seems reasonable, which also depends on the accuracy of the estimation of the respective CTFS.
Table 2.1: Example 2.6: Accuracy of estimates

Example 2.7. This example shows that for different quantiles, the bases of CQFS may be different. Let $p = q = 4$,

$$Y = 1 + X_{11} + (1 + 1.5X_{21})\epsilon,$$

where the distribution of $\epsilon$ is standard normal or student’s $t$ distribution with degrees of freedom 1 or 3. For this example, the quantile folding subspaces are different from the central folding subspace. Define $\beta(\tau) = (1, 1.5F^{-1}(\tau), 0, 0)^T$, for $0 < \tau < 1$, where $F$ is the CDF for standard normal, $t_1$ or $t_3$ random variable. Note that, if $\epsilon$ is a $t_1$ random variable, the expected value of $\epsilon$ is undefined and thus the corresponding central mean folding subspace is undefined as well. If $\epsilon$ is a standard normal or $t_3$ random variable, $S_{Y|\circ X_o} = S(e_1) \otimes S(\beta(.5), e_2)$ with $d = 2, r = 1$. In contrast, $S_{E(Y|\circ X_o)} = S_{M(Y|\circ X_o)} = S(e_1) \otimes S(\beta(.5))$ and $S_{Q_r(Y|\circ X_o)} = S(e_1) \otimes S(\beta(\tau))$ with $d = 1, r = 1$. If $\epsilon$ is a $t_1$ random variable, then $S_{Y|\circ X_o} = S(e_1) \otimes S(\beta(.5), e_2)$ with $d = 2$ and $r = 1$. However, $S_{M(Y|\circ X_o)} = S(e_1) \otimes S(\beta(.5))$ and $S_{Q_r(Y|\circ X_o)} = S(e_1) \otimes S(\beta(\tau))$ with $d = 1$ and $r = 1$. The benchmark distance for $S_{M(Y|\circ X_o)}$ or $S_{Q_r(Y|\circ X_o)}$ is 1.367.

The accuracy in Table 2.2 increases as sample size increases and the accuracy decreases when error distribution switches from normal distribution to $t_3$ and from $t_3$ to $t_1$ or switches from $\tau = 0.5$ to $\tau = 0.75$ same as in Example 2.1. The estimated percentage for correctly identifying dimensions is in the same change pattern as in the CQFS estimation accuracy for all the models.

</table>
Example 2.8. We also consider the Example 2 in Xue and Yin (2012),

\[
Y = X_{11}/(0.5 + (X_{21} + 1.5)^2) + 0.2 \times \epsilon, \quad (2.5.1)
\]

whose corresponding vector-valued model can be found in Li (1991) and Xia et al. (2002).

We set \( p = q = 5 \). Here, \( S_{Y|\text{vec}(X)} = S_{E(Y|\text{vec}(X))} = S_{Y|\circ X^\circ} = S_{E(Y|\circ X^\circ)} = S_{M(Y|\circ X^\circ)} = S_{Q_{y\circ}(Y|\circ X^\circ)} = S(e_1) \otimes S(e_1, e_2) \). Thus, \( d = 2 \) and \( r = 1 \) and the benchmark distance is 1.916.

As shown in Table 2.3, for Example 2.8, the accuracy of estimating CQFS and percentage for correctly estimating the dimensions follow the same pattern as in the two examples before. As sample size increase, the accuracy and correct percentage increase as we expect.

2.6 Application

In this section, we apply the estimation methods to the primary biliary cirrhosis (PBC) data set used in Chapter 1. We consider forging the central median dimension folding space of the repeatedly measured longitudinal data. Concentrating on the median arises that the median often has higher efficiency than the mean for skewed data and always has an easy interpretation. We adopt the primary biliary cirrhosis (PBC) data set used in Xue and Yin (2012) to illustrate our method. Same as in Xue and Yin (2012), we have a univariate response $Y$ and a $3 \times 4$ matrix-valued predictor $X$. The measurements of bilirubin, albumin level and prothrombin time are recorded at time point 6 month, 1 year, 2 year and 3 year. And the sample size $n$ is 187.

Literature that comments on quantile regression for longitudinal data includes Koenker (2004), Geraci and Bottai (2007) and Fu and Wang (2012), Koenker (2004) proposed a weighted composite quantile regression (Zou and Yuan, 2008 and Kai, Li and Zou, 2010) model with fixed effects and by combining $L_1$ shrinkage (Tibshirani, 1996). Koenker (2004) considered the penalized quantile regression model for longitudinal data. However, we consider the quantile regression for repeated measured longitudinal data from the aspect of dimension folding.

We firstly standardize $X$ and apply the modified BIC criterion to estimate $d$ and $r$ of the central median folding space. We have that $\hat{d} = \hat{r} = 1$ same as for the central mean folding space. Applying the refined estimation method and transforming the estimated bases in $Z$-scale back to the $X$-scale, the estimated bases in $X$-scale are
\[ A = (\alpha_1, \alpha_2, \alpha_3)^\top = (0.12369641, -0.9905826, -0.05869675)^\top \] and \[ B = (\beta_1, \beta_2, \beta_3, \beta_4)^\top = (-0.2740056, -0.1680333, -0.2602606, -0.910467)^\top. \] The estimated bases are quite close to those of the central mean folding subspace. The Frobenius norm between the two spaces is 0.1594707 comparing to the benchmark distance 1.349.

In order to test the significance of each coefficient in \( A \) and \( B \), we compute their 95% bootstrap confidence intervals respectively with 1000 bootstrap samples. The confidence intervals in Table 2.4 indicate albumin level and time point year 3 are significant at 0.05 level. The positive relationship between albumin level and the transplant-free or survival time is consistent to the medical outcome (Shapiro, Smith and Schaffner 1979). In the contrast, for the central mean dimension folding subspace, Xue and Yin (2012) found biliribin, albumin level and time year 3 are significant variables. Because the albumin levels can suggest liver disease and albumin testing is used in a variety of settings to help diagnose liver disease, to monitor disease progression, and time point year 3 reflects the progressive nature of the disease, the result for the central median dimension folding subspace is plausible. A summary plot of the response versus the reduced predictor and predicted model based on 50% quantile smoothing spline (Koenker, Ng and Portnoy, 1994) is shown in Figure 2.1. To fit the median quantile prediction model, we implement the “R” function “qsreg” from package “fields” (Oh et al., 2004; Lee and Cox, 2010). The fitted smoothing spline for the central median folding space looks pretty good and is quite similar to the spline plot in Xue and Yin (2012).

Figure 2.1: Summary plot and predicted model
2.7 Generalization to array-valued predictors

In this section, we briefly discuss how to extend the theory of dimension folding for a functional of conditional distribution of matrix-valued objects to array-valued predictors. Let $X = \{X_{j_1, j_2, \ldots, j_k} : j_1 = 1, \ldots, p_1, \ldots, j_k = 1, \ldots, p_k\}$ be a $k$-way random array of dimension $p_1 \times \cdots \times p_k$. Parallel the definition of central $T$ dimension folding for matrix-valued predictor we generalize the definition to the array-valued predictor as follow:

**Definition 2.2.** If there are matrices $\alpha_i \in \mathbb{R}^{p_i \times d_i}$ ($d_i \leq p_i$) for $i = 1, \ldots, k$ such that $T(x)$ depends on $x$ only through $(\alpha_k \otimes \cdots \otimes \alpha_1)^T \text{vec}(x)$, that is $T(x) = T(x^*)$ whenever $(\alpha_k \otimes \cdots \otimes \alpha_1)^T \text{vec}(x) = (\alpha_k \otimes \cdots \otimes \alpha_1)^T \text{vec}(x^*)$, then the column space of $\alpha_k \otimes \cdots \otimes \alpha_1$ is called a $k$-way dimension folding space for the functional $T$, or a $k$-way $T$ dimension folding space.

**Definition 2.3.** If the intersection of all the $k$-way $T$ dimension folding spaces as defined in Definition 2.2 itself is a $k$-way $T$ dimension folding space then it is called the $k$-way central $T$ dimension folding space for $Y$ on the array-valued predictor $X$. We write this space as $S_{Y|\circ X \circ}^k(T)$.

When $k = 1$, $S_{Y|\circ X \circ}^1(T)$ usually written as $S_{Y|\circ X \circ}(T)$ for conciseness is the central $T$ dimension folding space defined in Definition 2.1. Similar theory on $S_{Y|\circ X \circ}^k(T)$ and estimation methods on $S_{Y|\circ X \circ}^k(T)$ can be established straightforwardly from previous sections.
2.8 Conclusion

In this chapter, we establish the theory of sufficient dimension folding for a general functional, $T$, of the conditional distribution of matrix-/array-valued objects. We generalize the sufficient dimension folding and sufficient mean dimension folding spaces into the frame of sufficient functional $T$ dimension folding space and propose the central variance and central $k$-th moment dimension folding spaces. We construct the relationship between local central $T$ folding space and the central $T$ folding space based on which we propose a class of local estimation methods. We also introduce a modified BIC criterion to estimate the dimensions of the proposed central $T$ folding space. Besides, we consider the dimension folding for the quantile regression for the repeated measured longitudinal data. We illustrate our method by analyzing the primary biliary cirrhosis data used in Xue and Yin (2012). To evaluate the significance of individual variable, we adopt the bootstrap method to calculate the 95% confidential interval for each coefficient in the directions of the central $T$ folding space. However, there is a challenge to investigate the asymptotic properties of the quantile dimension folding and we propose it as our further research.
2.9 Appendix

Proof of Lemma 2.1:

That 2 $\Rightarrow$ 1 is obviously. Only need to show 1 $\Rightarrow$ 3 and 3 $\Rightarrow$ 2.

1 $\Rightarrow$ 3. Let $t_1$ and $t_2$ be any two matrices in $\mathbb{R}^{p \times q}$ such that $A^t t_1 B = A^t t_2 B$ and $\Sigma_A \in \mathbb{R}_+^{p \times p}$, $\Sigma_B \in \mathbb{R}_+^{q \times q}$ such that 1 holds. Then we have

\[
f(t_1) = f[P^T(\Sigma_A)t_1P(\Sigma_B)]
\]

\[
= f[\Sigma_A A(A^T \Sigma_A A)^{-1}(A^T t_1 B)(B^T \Sigma_B B)^{-1} B^T \Sigma_B]
\]

\[
= f[\Sigma_A A(A^T \Sigma_A A)^{-1}(A^T t_2 B)(B^T \Sigma_B B)^{-1} B^T \Sigma_B]
\]

\[
= f[P^T(\Sigma_A)t_2P(\Sigma_B)]
\]

which tells us that $f$ depends on $t$ only through $A^t B$.

3 $\Rightarrow$ 2. Let $\Sigma_A$ be any element $\in \mathbb{R}_+^{p \times p}$ and $\Sigma_B$ be any element $\in \mathbb{R}_+^{q \times q}$. Take $t_1 = t$ and $t_2 = P^T(\Sigma_A)tP(\Sigma_B)$. Since $P(\Sigma_A)$ and $P(\Sigma_B)$ are projections onto $\mathcal{S}(A)$ and
\( S(B) \) accordingly, then \( A = P(\Sigma_A)A \) and \( B = P(\Sigma_B)B \). And further

\[
A^t_1B = A^tB = [P(\Sigma_A)A]^tP(\Sigma_B)B \\
= A^tP^t(\Sigma_A)tP(\Sigma_B)B \\
= A^t_2B
\]

Since \( f \) is a function of \( A^tB \), \( f(t) = f(P^t(\Sigma_A)tP(\Sigma_B)) \).

**Proof of Proposition 2.1:** Suppose \( \alpha_L \) is a \( p \times d \) matrix whose columns form a basis of \( S_{Y|Z}(T) \) and \( \beta_R \) is a \( q \times r \) matrix whose columns form a basis of \( S_{Y|Z}(T) \).

Since \( Z = A^tXB \) and \( A \) and \( B \) are full rank, by lemma 2.1

\[
T_X(X) = T_Z(Z) = T_Z(P^t(\Sigma_\alpha_L)ZP(\Sigma_\beta_R)) \\
= T_X(P^t(\Sigma_\alpha_L)A^tXBP(\Sigma_\beta_R)) \\
= T_X([AP(\Sigma_\alpha_L)]^tX[BP(\Sigma_\beta_R)])
\]

\( \Rightarrow \) \( AP(\Sigma_\alpha_L) \) is a T-left dimension folding space for \( Y|X \) and \( BP(\Sigma_\beta_R) \) is a T-right dimension folding space for \( Y|X \).

\( \Rightarrow \) \( S(A_0) \subseteq S(AP(\Sigma_\alpha_L)) = AS(P(\Sigma_\alpha_L)) \) and \( S(B_0) \subseteq S(BP(\Sigma_\beta_R)) = BS(P(\Sigma_\beta_R)) \)

\( \Rightarrow \) \( S_{Y|\cdot}(T) \subseteq (B \otimes A)S_{Y|\cdot}(T) \).
And,

\[ T_Z(Z) = T_X(X) = T_Z(P^T(\Sigma_{A_0})X \Sigma_B) \]

\[ = T_Z(P^T(\Sigma_{A_0})A^T A^T X B B^{-1} P(\Sigma_{B_0})) \]

\[ = T_Z([A^T P(\Sigma_{A_0})]^T Z [B^{-1} P(\Sigma_{B_0})]) \]

\( \Rightarrow \) \( A^T P(\Sigma_{A_0}) \) and \( B^{-1} P(\Sigma_{B_0}) \) are a T-left- or right– dimension folding space for \( Y|Z \).

\( \Rightarrow \) \( S(\alpha_L) \subseteq S(A^T P(\Sigma_{A_0})) = A^T S(P(\Sigma_{A_0})) \) and \( S(\beta) \subseteq S(B^{-1} P(\Sigma_{B_0})) = B^{-1} S(P(\Sigma_{B_0})) \)

\( \Rightarrow \) \( S_{Y|$^{|P}$X_0}(T) \subseteq (B \otimes A)p_{Y|$^{|P}$X_0}(T) \)

\( \Rightarrow \) \( S_{Y|$^{|P}$X_0}(T) = (B^{-1} \otimes A^T) S_{Y|$^{|P}$X_0}(T) \).

**Proof of Proposition 2.2:** We follow the proof of Proposition 2 in Yin and Li (2012). However, we work on a matrix predictor instead of a vector. We write a general form of \( T_\Delta(x) = T_\Delta(y|x) \) and \( T_\Delta(x) \) may or may not depend on \( Y \). For example, the local density \( p_\Delta(y|x) \) depends on \( y \) but the local mean function \( E_\Delta(y|x) \) does not depend on \( y \). We use \( y \) in the form of \( T_\Delta \) without confusion.

Define \( \beta = B \otimes A \) and it is sufficient to show for any \( \alpha \in \mathbb{R}^{pq \times 1} \), \( \alpha^T \beta = 0 \) iff

\[ \alpha^T \frac{\partial}{\partial \text{vec}(x)} T_\Delta(y|x) = 0 \] for all \((x, y) \in \Delta \). By the chain rule of differentiation,

\[ \frac{\partial}{\partial \text{vec}(x)} T_\Delta(y|x) = \beta \frac{\partial}{\partial \text{vec}(s)} T_\Delta(y|s) \]. Thus, \( \alpha^T \beta = 0 \) implies that \( \alpha^T \frac{\partial}{\partial \text{vec}(x)} T_\Delta(y|x) = 0 \) for all \((x, y) \in \Delta \).
The other way can be showed by contradiction. Assume that there exists \( \mathbf{a}_0 \in \mathbb{R}^{pq} \) such that \( \mathbf{a}^\top_0 \frac{\partial}{\partial \text{vec}(\mathbf{x})} T_\Delta(y|x) = 0 \) for all \( (\mathbf{x}, y) \in \Delta \), but \( \mathbf{a}_0^\top \mathbf{b} \neq 0 \). Then \( \xi_1 = \mathbf{b}^\top \mathbf{a}_0 \| \mathbf{b}^\top \mathbf{a}_0 \| \) is a nonzero \( dr \times 1 \) vector. Therefore, \( \mathbf{a}^\top_0 \frac{\partial}{\partial \text{vec}(\mathbf{x})} T_\Delta(y|x) = \mathbf{b}^\top \frac{\partial}{\partial \text{vec}(\mathbf{s})} T_\Delta(y|s) = 0 \) implies that \( \xi_1^\top \frac{\partial}{\partial \text{vec}(\mathbf{s})} T_\Delta(y|s) = 0 \). Then the directional derivative of \( T_\Delta \) as a function of \( \text{vec}(\mathbf{s}) \) along \( \xi_1 \) is always 0. Thus, \( T_\Delta(y|s) = T_\Delta(y; s) \) is a constant along \( \xi_1 \), which means \( T_\Delta(y; s + t\xi) = T_\Delta(y; s) \) for all \( t \in \mathbb{R} \).

We can expand \( \xi_1 \) to form an orthogonal basis for \( \mathbb{R}^{dr} \), say, \( A_\xi = (\xi_1, \ldots, \xi_{dr}) \). Define \( v = A_\xi^\top \text{vec}(\mathbf{s}) = (v_1, \ldots, v_{dr})^\top \), then \( T_\Delta(y; s) = T_\Delta(y; A_\xi v) \), and \( \frac{\partial}{\partial v_1} T_\Delta(y; A_\xi v) = \xi_1^\top \frac{\partial}{\partial \text{vec}(\mathbf{s})} T_\Delta(y|s) = 0 \). Therefore, \( T_\Delta(y; A_\xi v) \) does not depend on \( v_1 \). And thus \( T_\Delta(y|s) = T_\Delta(y; s) = T_\Delta(y; A_\xi v) \) can be written as a function \( g(y; v_2, \ldots, v_{dr}) = g(y; \xi_1^\top \mathbf{b}^\top \mathbf{x}, \ldots, \xi_{dr}^\top \mathbf{b}^\top \mathbf{x}) \).

Then \( \mathbf{b} \xi_2, \ldots, \mathbf{b} \xi_{dr} \) is a local CTFS with structural dimension \( dr - 1 \), which is contradicts to the local CTFS has dimension \( dr \). The proof is completed.

**Proof of Proposition 2.3:** The proof can be easily extended from the proof of Proposition 3 in Yin and Li (2012). Here, we work on a matrix predictor instead of a vector predictor.

For \( (\mathbf{x}, y) \in \Delta \), we have

\[
f_\Delta(\mathbf{x}, y) := f((\mathbf{x}, y)|(\mathbf{X}, Y) \in \Delta) = \frac{f(\mathbf{x}, y)}{P_\Delta}, \tag{2.9.1}
\]
where $\mathbb{P}_\Delta$ is the probability $(X, Y) \in \Delta = \int \int f(x, y)dydx$. Let $f_{\Delta}(x) = \int f(x, y)dy$, then

$$f_{\Delta}(x) := f(x|(X, Y) \in \Delta) = \frac{f_{\Delta}(x, y)}{\mathbb{P}_\Delta}. \quad (2.9.2)$$

Define $w = w(y) = 1$ if $y \in \Delta_y$, and 0, otherwise. We then have

$$f(w = 1|x) := E_{(Y|X=x)}w(Y) = \mathbb{P}(w(y) = 1|x),$$

which means that

$$f(w = 1|x) = \int_{\Omega_y} w(y)f(y|x)dy = \int_{\Delta_y} f(y|x)dy = f_{\Delta_y}(x)/f(x). \quad (2.9.3)$$

Combining (2.9.1),(2.9.2) and (2.9.3), we have

$$f_{\Delta}(y|x) = \frac{f_{\Delta}(x, y)}{f_{\Delta}(x)} = \frac{f(x, y)}{f_{\Delta_y}(x)} = \frac{f(y|x)}{f(w = 1|x)},$$

or,

$$f(y|x) = f_{\Delta}(y|x)f(w = 1|x). \quad (2.9.4)$$

Suppose $A_0$ and $B_0$ is a basis matrix of $\mathcal{S}_{Y|x}$ and $\mathcal{S}_{Y|x_0}$, respectively. Then $F_{Y|x}(\cdot|x) = F_{Y|x}(A_0^TxB_0)$ by the definition of CFS. Thus, $f(y|x) = f(y|A_0^TxB_0)$, and $f(w = 1|x) = f(w = 1|A_0^TxB_0)$, since $w = 1$ is a function of $y$. By (2.9.4), we have for any $(x, y) \in \Delta$,
\[ f_\Delta(y|x) = f_\Delta(y|A_0^TxB_0). \]

Therefore, \( F_{\Delta(Y|X)}(\cdot|x) = F_{\Delta(Y|X)}(\cdot|A_0^TxB_0). \) By the definition of \( T_\Delta(x), \) the subspace spanned by the columns of \( A_0 \) forms a central T-left dimension folding subspace, and \( B_0 \) forms a central T-right dimension folding subspace. And by the definition of local CTFS, we have that \( S_{Y|X}(T_\Delta) \subseteq S_{Y|X}. \)

If \( \Delta_y = \Omega_y, \) then \( w = 1 \) for all \( y. \) For any \( x \in \Omega_x, \) there exist \( \Delta_x \) such that \( x \in \Delta_x \subseteq \Omega_x. \)

By (2.9.4), we have \( f_\Delta(y|x) = f(y|x), \) and we have \( T_\Delta(x) = T(x). \) From Proposition 2.2, we have:

\[
S\{S_{Y|X_0}(T_\Delta), \Delta = \Delta_x \times \Omega_Y \ for \ all \ x \in \Omega_X\} = S_{Y|X_0}(T).
\]
Bibliography

Chapter 3

Sufficient dimension folding based on an ensemble of minimum average variance estimators

3.1 Introduction

To remedy the defect that folded-MAVE method can not recover directions outside the CMFS, we adopt the idea of ensemble (Yin and Li, 2011) to cover the CFS by the unison of several central mean dimension folding subspaces. We consider a general family $\mathfrak{F}$ of functions of $Y$ and, for each $f \in \mathfrak{F}$, $\mathcal{S}_{E[f(Y)\mid \delta X]}$ is the CMFS for the conditional mean $E[f(Y)\mid X]$. If the subspace spanned by the collection of subspaces $\{\mathcal{S}_{E[f(Y)\mid \delta X]} : f \in \mathfrak{F}\}$ equals to the CFS, $\mathfrak{F}$ is said to be characterizing the CFS. The functions $f_1, \ldots, f_m$ can
be randomly sampled from \( \mathcal{F} \) according to a probability measure on \( \mathcal{F} \) and the assembly of the CMFS \( \mathcal{S}_{E[f(Y)|X_0]}, l = 1, \ldots, m \) recovers the CFS.

In this chapter, we construct iterative algorithms named as folded-OPG ensemble and folded-MAVE ensemble and show the ensemble estimators can exhaustively recover the CFS. The properties of folded ensemble methods can be investigated based on the result in Yin and Li (2011) since \( Y \perp X | A^T X B \) or \( Y \perp E(Y|X)|A^T X B \) are equivalent to \( Y \perp \text{vec}(X)|(B \otimes A)^T \text{vec}(X) \) or \( Y \perp E[Y|\text{vec}(X)]|(B \otimes A)^T \text{vec}(X) \), where \( \text{vec}(\cdot) \) is an operation that stacks a matrix into a vector column by column. Nevertheless, to exhaustively estimate the CFS, an iterative procedure is indispensable in the folded ensemble methods. We mainly focus on the ensemble algorithms on matrix-valued predictor and a brief extension of the ensemble idea to the array-valued predictor is followed.

In Section 3.2, we extend the theory on characterizing central subspace to the central folding subspace. In Section 3.3, we introduce the algorithms of folded-MAVE ensemble and its variation, folded-OPG ensemble, to estimate the central folding subspace. In Section 3.4, we introduce a cross validation criterion for estimating the number of directions in CFS. We then summarize our future work.

### 3.2 Estimating the CFS through CMFS

Characterizing the central folding subspace is carried out by combining the dimension folding subspaces for \( E[f(Y)|X] \) in unity, as long as the samplings of function \( f \) are
sufficiently dense. Suppose $X \in \mathbb{R}^{p \times q}$ is a $p \times q$ random matrix with its support $\Omega_X$ and $Y$ is a $s$-dimensional random vector with its support $\Omega_Y$. A transformation $f$ can project a vector-valued $Y$ to the scalar field $\mathbb{R}$. Let $\mathcal{F}$ be a family of functions $f : \Omega_Y \to \mathbb{F}$, where $\mathbb{F}$ can be the set of complex numbers $\mathbb{C}$ or real numbers $\mathbb{R}$. And let $P_S$ be the projection onto a space $S$. Then for the $\mathcal{S}_{E[f(Y)|X]}$, the CMFS of conditional mean $E[f(Y)|X]$, we have

$$E[f(Y)|X] = E[f(Y)|P_{\mathcal{S}_{E[f(Y)|X]}}\text{vec}(X)]. \quad (3.2.1)$$

And for the CFS, $\mathcal{S}_{Y|X}$, we have

$$Y \parallel X|P_{\mathcal{S}_{Y|X}}\text{vec}(X). \quad (3.2.2)$$

**Definition 3.1.** Let $\mathcal{F}$ be a family of measurable $\mathbb{F}$-valued functions defined on $\Omega_Y$. If

$$\{\mathcal{S}_{E[f(Y)|X]} : f \in \mathcal{F}\} = \mathcal{S}_{Y|X}, \quad (3.2.3)$$

the family $\mathcal{F}$ is said to characterize the central folding subspace.

Let $F_Y$ denote the distribution of $Y$, and let $L_1(F_Y)$ be the class of functions $f(Y)$ such that $E|f(Y)| < \infty$, together with the norm $E|f(Y)|$. If $f \in L_1(F_Y)$, $E[f(Y)|X]$ is finite. Let $L_2(F_Y)$ be the class of functions $f(Y)$ with finite variances, together with the inner product $\langle f_1, f_2 \rangle = E[f_1(Y)f_2(Y)]$. We denote the subspace on the left hand side
of (3.2.3) by $S(\mathcal{F})$. We have the following lemma which can be proved similarly to that of Yin and Li (2011).

**Lemma 3.1.** Suppose that $\mathcal{F} \subseteq L_1(F_Y)$, then,

1. $S(\mathcal{F}) \subseteq S_{Y|\circ X_0}$.
2. If (3.2.1) being satisfied for all $f \in \mathcal{F}$ implies (3.2.2), then $S_{Y|\circ X_0} \subseteq S(\mathcal{F})$.

Let $\mathcal{B}$ be the family of measurable indicator functions of $Y$. That is, $\mathcal{B} = \{I_B : B$ is a Borel set in $\Omega_Y\}$. Then $\mathcal{B} \subseteq L_2(F_Y)$. The following theorem guarantees that several families can be adopted to characterize the CFS.

**Theorem 3.1.** If $\mathcal{F}$ is a subset of $L_2(F_Y)$ that is dense in $\mathcal{B}$, then $\mathcal{F}$ characterizes the central dimension folding subspace.

**Example 3.1.** (Polynomials) Let $\mathcal{F} = \{Y^t : t = 1, 2, \ldots\}$. Then $S_{E[f(Y)|\circ X_0]} = S_{E[Y^t|\circ X_0]}$. If the conditional moment generating function $E(e^{\xi Y}|X)$ is finite in an open interval that contains 0, then $\mathcal{F}$ is dense in $L_2(F_Y)$, and hence characterizes $S_{Y|\circ X_0}$.

**Example 3.2.** (Kernel density) Let $b > 0$ and $H$ be a symmetric probability density function defined on $\mathbb{R}$. Let $\mathcal{F} = \{b^{-1}H((y-t)/b) : t \in \mathbb{R}, b \in \mathbb{R}^+\}$, which is dense in $L_2(F_Y)$ when $H$ is the Normal density and thus $S_{Y|\circ X_0}$ can be recovered by estimating $S_{E[f(Y)|\circ X_0]}$ for $f \in \mathcal{F}$.

**Example 3.3.** (Slices) Let $\mathcal{F} = \{I_{(\infty,t]}(y) : t \in \mathbb{R}\}$. Then $\mathcal{F}$ is dense in $\mathcal{B}$ and can be used to characterize $S_{E[f(Y)|\circ X_0]}$. 

93
Example 3.4. (Box-Cox transformations) Let $Y$ be a nonnegative random variable, and consider the family of transformations

$$f_t(y) = \begin{cases} 
  \frac{y^{t} - 1}{t} & t \neq 0 \\
  \log(y) & t = 0 
\end{cases}, \quad \text{(3.2.4)}$$

which contains the family in Example 3.1 and thus it characterizes the CFS.

Example 3.5. (Characteristic function) Let $\mathcal{F} = \{e^{\imath t}y : t \in \mathbb{R}\}$, where $\imath = \sqrt{-1}$. Note that $E(e^{\imath tY}|X)$ is simply the conditional characteristic function of $Y|X$ and this family is dense in $L_2(F_Y)$.

Theorem 3.2 below whose proof follow the proof of Theorem 2.2 in Yin and Li (2011), demonstrates that, with probability 1, the CFS can be characterized by a finite number of functions in a characterizing family.

Let $B = (\beta_1, ..., \beta_{dr})$ be an orthogonal basis for the central folding subspace, $\mathcal{S}_{Y|\circ X_0}$, whose dimensions are $d$ and $r$. We will randomly sample $T_1, \ldots, T_m$ from $\Omega_T$ and assume that these random elements are defined on a measurable space $(\Omega, \mathcal{A})$. Then $\Omega_T$ is interpreted as the range of the mapping $T_i : \Omega \to \Omega_T$ and we denote a generic member of $\Omega$ by $\omega$.

Theorem 3.2. Suppose that $\mathcal{F}$ characterizes the central folding subspace, $T_1, T_2, \ldots$ is an i.i.d. sequence of random variables supported on $\Omega_T$ and, for each integer $m$, $B_0(T_1, ..., T_m)$ is an orthogonal basis matrix of $\{\mathcal{S}_{E[f_{T_i}(Y)|\circ X_0]} : i = 1, \ldots, m\}$. Then the
following event has probability 1:

\{ \omega \in \Omega : \text{there is an integer } m_0(\omega) \text{ such that,} \\
for all } m \geq m_0(\omega), \ \text{Span}(B_0(T_1(\omega), \ldots, T_m(\omega))) = \text{Span}(B) \}.

### 3.3 Estimate the CFS through *folded-MAVE*: Algorithm

The *folded-MAVE* can exhaustively estimate directions in the CMFS only. To remedy this deficiency, we can adopt the idea of sliced regression (SR, Wang and Xia, 2008) to enable the *folded-MAVE* to recover directions in the CFS. Let \(-\infty = s_0 < s_1, \ldots, < s_H = +\infty\) be the pre-selected grid point to slice the response, and let \(v_k = I(s_{(k-1)} < Y < s_k)\), where \(I(\cdot)\) is the indicator function, then the CMFS of \((v_1, \ldots, v_H)^T\) coincides with the CFS of \(Y\).

We can synthesize the *folded-MAVE* ensemble which extends the estimation of CMFS to the estimation of CFS in more general conditions. We call it *folded-MAVE* ensemble. folded-OPG ensemble as a variation of *folded-MAVE* ensemble is also considered.
3.3.1 Folded MAVE ensemble

Suppose $X \in \mathbb{R}^{p \times q}$ defined on $\Omega_X$, $Y \in \mathbb{R}^s$ defined on $\Omega_Y$. We only consider the parametric characterizing family $\mathcal{F}$ in this chapter. That is $\mathcal{F}$ is of the form $\{f_t : t \in \Omega_T\}$ where $\Omega_T$ is a subset of a Euclidean space. Let $\mathcal{F} = \{I_{(-\infty,t]}(Y) : t \in \mathbb{R}\}$, then for $f \in \mathcal{F}$, the unison of estimations of $\mathcal{S}_{E(f(Y)|X)}$ is $\mathcal{S}_{Y|X}$. Thus, our previous modification of folded-MAVE based on SR is indeed a special case of the folded-MAVE ensemble.

Let $f_t(y) = f_t(y,1) + if_t(y,2)$, where $f_t(y,1)$ and $f_t(y,2)$ are the real and imaginary parts of $f_t(y)$, and let $T$ be a random vector defined on $\Omega_T$ with distribution $F_T$. The population level objective function can be constructed by applying the folded-MAVE procedure to the transformed response $f_t(Y)$ and integrating with respect to the distribution $F_T$. It is formulated as:

$$
\sum_{l=1}^{2} \int_{\Omega_T \times \Omega_X} E\{[f_t(Y,l) - c_l(x) - a_l^T(x)A^T(X-x)Bb_l(x)]^2K_h[(B \otimes A)^T \text{vec}(X-x)]\}dF_X(x)dF_T(t).
$$

(3.3.1)

We minimize the function (3.3.1) over all $c_l(\cdot) \in \mathbb{R}$, all $a_l(\cdot) \in \mathbb{R}^d$, $b_l(\cdot) \in \mathbb{R}^r$, all $p \times d$ constant matrices $A$ and all $q \times r$ constant matrices $B$, $l = 1, 2$.

At the sample level, let $T_1, \ldots, T_m$ be an independent sample from $F_T$, we minimize the objective function

$$
\sum_{l=1}^{2} \sum_{k=1}^{m} \sum_{j=1}^{n} \sum_{i=1}^{n} \rho_j w_{ij}(h)[f_{T_k}(Y_i,l) - c_{jk}(l) - a_{jk}(l)^T A^T(x_i - x_j)Bb_{jk}(l)]^2
$$

(3.3.2)
over scalars \( \{c_{jk}(l) : j = 1, \ldots, n, k = 1, \ldots, m, l = 1, 2\} \), \( \{a_{jk}(l) \in \mathbb{R}^d : j = 1, \ldots, n, k = 1, \ldots, m, l = 1, 2\} \), \( \{b_{jk}(l) \in \mathbb{R}^r : j = 1, \ldots, n, k = 1, \ldots, m, l = 1, 2\} \), \( p \times d \) matrices \( A \) and \( q \times r \) matrices \( B \). The coefficient \( \rho_j \) is the same as defined in (1.3.5).

For fixed \( a_{jk}(l) \in \mathbb{R}^d \), \( A \in \mathbb{R}^{p \times d} \), \( B \in \mathbb{R}^{q \times r} \), minimizing (3.3.2) jointly over \( c_{jk}(l), b_{jk}(l) \) for \( j = 1, \ldots, n, k = 1, \ldots, m, l = 1, 2 \), is equivalent to minimizing

\[
\sum_{i=1}^{n} \rho_j w_{ij}(h)[f_{T_k}(Y_i, l) - c_{jk}(l) - a_{jk}(l)^T A^T(x_i - x_j) B b_{jk}(l)]^2
\]  

(3.3.3)

individually. More specifically, we suggest the following \textit{folded-MAVE} ensemble procedures.

1. Generate \( a_{jk}(l) \in \mathbb{R}^d \) from \( N(0, 1) \). \( A \in \mathbb{R}^{p \times d} \), \( B \in \mathbb{R}^{q \times r} \) can be obtained from the folded OPG ensemble introduced later or generated from \( N(0, 1) \).

2. For fixed \( a_{jk}(l) \in \mathbb{R}^d \), \( A \in \mathbb{R}^{p \times d} \), \( B \in \mathbb{R}^{q \times r} \), the least-squares solution of (3.3.3), for each triplet \( (j, k, l) \), is

\[
\begin{bmatrix}
\hat{c}_{jk}(l) \\
\hat{b}_{jk}(l)
\end{bmatrix} = \left[ \sum_{i=1}^{n} \rho_j w_{ij}(h) \Delta_{ij}(a_{jk}(l), A, B) \Delta_{ij}^T(a_{jk}(l), A, B) \right]^{-1} \times \left[ \sum_{i=1}^{n} \rho_j w_{ij}(h) \Delta_{ij}(a_{jk}(l), A, B) f_{T_k}(Y_i, l) \right]
\]

where \( \Delta_{ij}(a_{jk}(l), A, B) = [1, (\text{vec}(x_i - x_j))^T(B \otimes A)(I_r \otimes a_{jk}(l))]^T \).
3. For fixed $c_{jk}(l), b_{jk}(l) \in \mathbb{R}^r$, $A \in \mathbb{R}^{p \times d}$, $B \in \mathbb{R}^{q \times r}$, the least-squares solution of (3.3.3), for each triplet $(j, k, l)$, is then

$$\hat{a}_{jk}(l) = \left[ \sum_{i=1}^{n} \rho_i w_{ij}(h) \Delta_{ij}(b_{jk}(l), A, B) \Delta_{ij}^T(b_{jk}(l), A, B) \right]^{-1} \times \left[ \sum_{i=1}^{n} \rho_i w_{ij}(h) \Delta_{ij}(b_{jk}(l), A, B)(f_{Tk}(Y_i, l) - c_{jk}(l)) \right],$$

where $\Delta_{ij}(b_{jk}(l), A, B) = [(\text{vec}(x_i - x_j))^T (B \otimes A)(b_{jk}(l) \otimes I_d)]^T$.

4. For fixed $c_{jk}(l), a_{jk}(l), b_{jk}(l)$ and $A$, $j = 1, \ldots, n$, $k = 1, \ldots, m$, $l = 1, 2$, the minimization of (3.3.2) is also a least-squares problem. The solution is

$$\text{vec}(\hat{B}) = \left[ \sum_{i=1}^{n} \rho_i w_{ij}(h) \Delta_{ij}(a_{jk}(l), b_{jk}(l), A) \Delta_{ij}^T(a_{jk}(l), b_{jk}(l), A) \right]^{-1} \times \left[ \sum_{i=1}^{n} \rho_i w_{ij}(h) \Delta_{ij}(a_{jk}(l), b_{jk}(l), A)(f_{Tk}(y_i, l) - c_{jk}(l)) \right],$$

where $\Delta_{ij}(a_{jk}(l), b_{jk}(l), A) = [I_r \otimes ((x_i - x_j)^T A)(b_{jk}(l) \otimes a_{jk}(l))]$ and the summation is over

$$(i, j, k, l) \in \{1, \ldots, n\} \times \{1, \ldots, n\} \times \{1, \ldots, m\} \times \{1, 2\}.$$

5. For fixed $c_{jk}(l), a_{jk}(l), b_{jk}(l)$ and $A$, $j = 1, \ldots, n$, $k = 1, \ldots, m$, $l = 1, 2$,

$$\text{vec}(\hat{A}^T) = \left[ \sum_{i=1}^{n} \rho_i w_{ij}(h) \Delta_{ij}(a_{jk}(l), b_{jk}(l), B) \Delta_{ij}^T(a_{jk}(l), b_{jk}(l), B) \right]^{-1} \times \left[ \sum_{i=1}^{n} \rho_i w_{ij}(h) \Delta_{ij}(a_{jk}(l), b_{jk}(l), B)(f_{Tk}(y_i, l) - c_{jk}(l)) \right].$$
where $\Delta_{ij}(a_{jk}(l), b_{jk}(l), B) = [(x_i - x_j)B \otimes I_d](b_{jk}(l) \otimes a_{jk}(l))$ and the summation is also over

$$(i, j, k, l) \in \{1, \ldots, n\} \times \{1, \ldots, n\} \times \{1, \ldots, m\} \times \{1, 2\}.$$

We iteratively estimate the parameters between the above five steps until convergence.

### 3.3.2 Folded OPG Ensemble

Let $\mathcal{F}, F_T, T_1, \ldots, T_m$ and $w_{ij}(h)$ be as defined in the previous section. For folded OPG ensemble, we minimize the objective function for each $j, k, l,$

$$\sum_{i=1}^{n} w_{ij}(h)[f_{T_k}(y_i, l) - c - a^T(x_i - x_j)b]^2$$

(3.3.4)

er over $(c, a, b) \in \mathbb{R} \times \mathbb{R}^p \times \mathbb{R}^q$ for each $j = 1, \ldots, n, k = 1, \ldots, m$ and $l = 1, 2$.

The folded-OPG ensemble is summarized as

1. Generate $a_{jk}(l) \in \mathbb{R}^p$ from $N(0, 1)$.

2. For fixed $a_{jk}(l)$, $\hat{c}_{jk}(l)$ and $\hat{b}_{jk}(l)$ that minimize (3.3.4) are

$$\begin{pmatrix} \hat{c}_{jk}(l) \\ \hat{b}_{jk}(l) \end{pmatrix} = \left[ \sum_{i=1}^{n} w_{ij}(h)\Delta_{ij}(a_{jk}(l))\Delta_{ij}^T(a_{jk}(l)) \right]^{-1} \left[ \sum_{i=1}^{n} w_{ij}(h)\Delta_{ij}(a_{jk}(l)) f_{T_k}(y_i, l) \right],$$

where $\Delta_{ij}(a_{jk}(l)) = (1, (\text{vec}(x_i - x_j))^T(I_q \otimes a_{jk}(l)))^T$. 

3. For fixed $c_{jk}(l)$ and $b_{jk}(l)$, $\hat{a}_{jk}(l)$ that minimizes (3.3.4) is

$$\hat{a}_{jk}(l) = \left[ \sum_{i=1}^{n} w_{ij}(h) \Delta_{ij}(b_{jk}(l)) \Delta_{ij}^{\top}(b_{jk}(l)) \right]^{-1} \left[ \sum_{i=1}^{n} w_{ij}(h) \Delta_{ij}(b_{jk}(l))(f_{Tk}(Y_{i},l) - c_{jk}(l)) \right],$$

where $\Delta_{ij}(b_{jk}(l)) = ((vec(x_{i} - x_{j}))^{\top}(b_{jk}(l) \otimes I_{p}))^{\top}$.

4. Compute the OPG matrices as:

$$\sum_{l=1}^{2} \sum_{k=1}^{m} \sum_{j=1}^{n} \rho_{j}\hat{a}_{jk}(l)\hat{a}_{jk}^{\top}(l), \quad (3.3.5)$$

and

$$\sum_{l=1}^{2} \sum_{k=1}^{m} \sum_{j=1}^{n} \rho_{j}\hat{b}_{jk}(l)\hat{b}_{jk}^{\top}(l). \quad (3.3.6)$$

The folded-OPG ensemble also involves iteratively estimating the $c_{jk}(l)$, $a_{jk}(l)$ and $b_{jk}(l)$. After convergence, $A$ and $B$ are the first $d$ and $r$ eigenvectors according to the $d$ and $r$ largest eigenvalues of (3.3.5) or (3.3.6) respectively.

### 3.4 Estimations of $d$, $r$ and choices of $\hat{\delta}$

In describing the foregoing algorithms we have assumed $d$ and $r$, the dimension of the $S_{Y|\mathbf{x}}$ and $S_{Y|X_{0}}$ respectively to be known. In practice those dimensions must also be estimated. We now propose a cross validation method to estimate $d$ and $r$. Let $\hat{A}$ and $\hat{B}$ be the estimated bases of $S_{Y|\mathbf{x}}$ and $S_{Y|X_{0}}$ respectively for a fixed working dimension $d_{0}$.
and $r_0$. Then the leave-one-out fitted value of $f_{T_k}(Y_j, \ell)$, for $j = 1, \ldots, n$, $k = 1, \ldots, m$, and $\ell = 1, 2$, is

$$\hat{\mu}_{kj}(d_0, r_0, \ell) = \sum_{i \neq j} K_{h}[(\hat{B} \otimes \hat{A})^T \text{vec}(X_i - X_j)] f_{T_k}(Y_i, \ell) / \sum_{i \neq j} K_{h}[(\hat{B} \otimes \hat{A})^T \text{vec}(X_i - X_j)].$$

The corresponding cross validation value is

$$\text{CV}(d_0, r_0) = \frac{1}{2mn} \sum_{\ell=1}^{2} \sum_{k=1}^{m} \sum_{j=1}^{n} [f_{T_k}(Y_j, \ell) - \hat{\mu}_{kj}(d_0, r_0, \ell)]^2.$$ 

To include the trivial case of $d_0 = 0$ or $r_0 = 0$, we define $\hat{\mu}_{kj}(0, r_0, \ell)$, $\hat{\mu}_{kj}(d_0, 0, \ell)$ and $\hat{\mu}_{kj}(0, 0, \ell)$ to be $(n-1)^{-1} \sum_{i \neq j} f_{T_k}(Y_j, \ell)$, so that $\text{CV}(d_0, r_0)$ is defined for all $d_0 = 0, \ldots, p$ and $r_0 = 0, \ldots, q$. The structural dimensions $d$ and $r$ are estimated by

$$(\hat{d}, \hat{r}) = \text{argmin}\{\text{CV}(d_0, r_0) : d_0 = 0, \ldots, p; r_0 = 0, \ldots, q\}.$$ 

In this chapter we pay special attention to the family determined by the characteristic function, as discussed in Example 3.5. That is,

$$\mathcal{F}_C = \{e^{\mu^T y} : \mu \in \mathbb{R}\}.$$ 

And we named the folded-OPG and folded-MAVE ensemble based on $\mathcal{F}_C$ as folded-OPG-$\mathcal{F}_C$ and folded-MAVE-$\mathcal{F}_C$. An advantage of the family $\mathcal{F}_C$ is that its members are bounded functions, and as such are relatively robust against the outliers in $Y$. Moreover,
it requires virtually no condition on the distribution of $Y$. Also note that when $t$ ranges over $\mathbb{R}^s$, the function $e^{t^Ty}$ fully recovers the joint information of the random vector $Y$.

Having prepared the basics above, we will investigate asymptotic properties and run simulations for the performance of the proposed methods, and apply them to some data sets in the future.
