DNA LEVEL CHARACTERISTICS AND PHENOTYPIC FEATURES REVEALED BY KNOCKOUT, OVEREXPRESSION AND ADDITION MUTANTS FOR DUPLICATION-RESISTANT GENES

by

CHENGBO ZHOU

(Under the Direction of Andrew H. Paterson)

ABSTRACT

Gene duplication provides raw material for evolution in the genomes of higher eukaryotes. The propensity for genes to return to single copy dosage after duplication varies, and is partly reflected by their copy numbers in other species. Arabidopsis single copy genes can be divided into subsets with different characteristics, including different likelihoods of showing knockout (KO) phenotypes. We are particularly interested in the subset that was consistently restored to single copy dosage after independent whole-genome duplications in multiple lineages, known as duplication-resistant (DR) genes. The recurring removal of duplicated gene copies is associated with gene function, as implied by GO terms enriched in DR genes, making functional study of DR genes an approach to decipher the basis of duplication resistance. In this study, we assessed Arabidopsis DR gene functions via their KO phenotypes. Compared to non-DR singletons, T-DNA insertion mutants of DR genes were not prone to exhibit phenotypes under stress conditions, showing a low occurrence of ABA and cold sensitive phenotypes and an overrepresentation of salt-related phenotypes. On the other hand, severe phenotypes, including visible seedling alternations and phenotypes indicative of homozygous lethality, occurred more

frequently in DR genes than other singletons. In addition, Arabidopsis genotypes with artificial duplication (Addition, AD) (OE, by coupling to 35S promoters) of DR genes were made, to examine the consequences of having multiple copies of these genes. Visible duplication effects, as reflected by AD phenotypes, were more likely to occur in DR genes than in other singletons. Seedling phenotypes, absent in AD lines, were found in OE lines at a higher percentage than KO mutants. As for other genes, duplication and overexpression of DR genes can also result in stress tolerance. Genes with both OE and KO phenotypes constitute approximately one third of DR genes with OE lines, indicating that dosage sensitivity may be responsible for duplication resistance of some DR genes.

ACKNOWLEDGEMENTS

To my advisor Professor Andrew Paterson, thank you for always being patient, supportive and awesome.

To Professor Kenneth Feldmann, thank you for making this project possible.

To my committee members, thank you all for joining my committee and for your help. I learnt a lot from the classes you taught.

To Ms. Katy Millward, thank you for teaching me all the techniques and for making the transgenic lines.

To Mr. Mitchell Feldmann, thank you for helping with the phenotype screen and taking the photographs.

To Ms. Susan Watkins, thank you for helping me with all the complicated forms. You are the best.

To Professor Brigitte Bruns, thank you for always encouraging me, for all your help and for being a truly amazing person.

To Ms. Carla Feldmann, thank you for taking good care of me while I was working on this project in Arizona.

To people in PBIO department and PGML, thank you for being nice, friendly and helpful.

To my friends and family, thank you for your love, support and always being there for me. I love you.

CHAPTER 1

INTRODUCTION

Gene duplication at various scales is an inevitable part of genome evolution [1]. Duplications of individual genes and small genomic segments served as a continuous source of duplicated genes [2, 3] and were responsible for the expansion of gene families involved in response to environmental stimuli [4, 5]. Whole genome duplications, followed by massive gene loss [6], restructured the genome, brought dramatic changes to metabolic networks, and sometimes led to the born of new species [7]. Many higher eukaryotes have experienced whole genome duplication or triplication [8, 9], which occurred most frequently in flowering plants [10-16]. The abundance of genome duplication events makes angiosperms an outstanding model to study fate after gene duplication [17], a part as important as duplication itself during genome evolution.

The various evolutionary fates after gene duplication [1] can be summarized into two, retention and loss, according to the current snapshot of genomes: some genes have multiple copies and others do not. Duplicates retention, accompanied usually by sequence and functional divergence, occurred to a small number of genes, thus was considered rare and non-random [6]. Consequently, factors contributing to duplication retention have been extensively studied and became relatively well-understood [18-20]. In contrast, duplicates removal via 'non-functionalization' [21], as a fate awaiting most genes [6], seems to be random and received less attention.

While many singletons may randomly revert back to single copy status after duplication, evidence supporting non-random loss of duplicates abound. In Arabidopsis, some genes were repeatedly restored to 'singleton' after subsequent whole genome duplications [22]. Moreover, the number of single copy genes conserved among multiple species is much higher than expected assuming random gene loss [23, 24], and only decreases slightly as more genomes are sampled [25]. In addition, the chance of staying single copy seems to be associated with gene function. Genes in specific functional categories show more gene loss than genome average [26, 27], and certain protein domains are enriched in singletons of Arabidopsis and Oryza [28].

The preference for single copy is most evident in duplication-resistant (DR) genes, which tend to be singletons or have low copy number in multiple plant species they were conserved in. Given that all angiosperms are paleo-polyploids [17], DR genes were capable of surviving multiple and independent genome duplications as single copy, thus revealed strong resistance to duplication. As a result, DR genes became a favorite research target to study non-random gene loss.

Several groups of DR genes fitting the above definition have been identified, and their characteristics described. Single copy genes shared between Arabidopsis and rice have shorter proteins and more introns than the genome averages, along with distinctive promoter sequence features indicative of housekeeping function [23]. A subset of these genes conserved as single copy in moss and alga has low dN/dS value, indicating that they were under purifying selection thus not a group of random genes [23]. The shared single copy genes among Arabidopsis, Populus, Vitis and Oryza have more exons, fewer known domains, and are overrepresented in specific functional categories such as chloroplast, plastid and DNA or RNA metabolism, compared to the rest of the genome [25]. The functional bias remained similar when the number

of species increased to twenty [29]. Genes conserved as single copy among all or most of 20 flowering plants are well conserved in non-plant species as well, suggesting that they tend to function in basic processes important to probably all living creatures [29]. Their presumable involvement in housekeeping functions is further supported by their high expression breadth [29]. Additional characteristics of these DR genes include high expression level and biased codon use [29].

While the distinctive features of DR genes offered no clear explanation for duplication resistance, some inspired hypothesis about possible contributors to the persistent single copy status. The enrichment of chloroplast-targeting genes, for example, led to 'Select single copy gene hypothesis', stating that the duplication of chloroplast-targeting DR genes might disturb the dosage balance with their chloroplast genome encoded partners [30]. The 'Dominant-negative mutation hypothesis', on the other hand, springs from the observation that many DR genes are components of protein complexes [29]. According to this hypothesis, a mutated duplicate copy may encode proteins that are capable of binding other components but form inactive complex instead. Experimental confirmation of these hypotheses would be valuable for future research on duplication resistance, thus motivates further exploration of DR genes' characteristics.

The overrepresented GO terms in DR genes associated duplication resistance with gene function. Being perhaps an indispensable piece to solve the duplication resistance puzzle, the function of DR genes is far from being fully explored. More definitive than predicted functions is empirical observation of phenotypic changes resulting from silencing a gene. For example, gene importance is more directly reflected on the severity of its loss-of-function phenotypes than the annotated function. Meanwhile, the presence of knockout (KO) phenotype may serve as a strong proof and present a visual outcome of predicted dosage balance perturbation.

Thanks to the abundance of mutant resources in Arabidopsis [31-35], KO phenotypes were available for many genes. Using the published phenotype datasets [36-38], features regarding to KO phenotypes of DR genes and other subsets of Arabidopsis single copy genes grouped by their copy numbers in four other plant species, were described in Chapter 1. A majority of DR genes were in lack of any reported KO phenotype, and mutants for some may have never been studied. Therefore, to complete DR genes' KO phenotype dataset, a platform for in-depth functional study, their T-DNA insertional mutants were ordered and phenotyped. Several stress conditions were applied for phenotyping, as conditional phenotypes were extremely diverse and normally invisible thus remain largely uninvestigated. Due to the similar reason, root phenotypes were searched for as well. The stress and root phenotypes from DR genes, along with striking seedling phenotypes shown under normal condition, were described and compared to other single copy genes in Chapter 2.

The single copy status of DR genes among plant species with varying evolutionary speed suggests a relatively fast removal of their duplicated copies, the presence of which may exert negative effect thus was selected against. To assess the direct outcome of gene duplication, addition (AD) lines were made, each containing a transgenic copy of a target gene. As dosage increase is usually the cause of duplication effect [39-41], overexpression (OE) lines, where target genes were overexpressed by the CaMV 35S promoter, were also used to visualize intensified versions of duplication effect, which may be too mild to detect sometimes. The two kinds of mutants were phenotyped similarly as the KO mutants. Phenotypes from AD and OE lines were presented and discussed in Chapter 3.

CHAPTER 2

LITERATURE REVIEW

BACKGROUND

Gene duplications in the genomes of higher eukaryotes

Duplication of DNA happens on various scales. Whole genome duplication (WGD), followed by gene loss and genome rearrangement, restructures a genome, provides raw material for evolution, and often precedes the emergence of new species. Many higher eukaryotes have experienced whole genome duplication or triplication. There was a WGD in a yeast ancestor before the divergence of S. cerevisiae and K. waltii [1]. Two whole genome duplications are thought to have happened in early vertebrate evolution [2], followed by an independent WGD in the fish lineage [1].

Genome duplications have been remarkably abundant in flowering plants, with WGDs in a seed plant common ancestor [3], an angiosperm common ancestor [3], both monocot and dicot lineages [4-6], and numerous lineage specific events [7-10]. Even 'model' plants with small genomes, such as Arabidopsis and Oryza, are paleo-polyploids, with the footprints of past WGD events evident in their genomes [11, 12]. The prevalence of polyploidy events in plants is thought to contribute to their evolutionary success [13, 14] and to their attributes as crops [15-21], making them suitable, if not the best, models for study of gene fates after duplication.

'Small scale duplications' (SSDs), i.e., of individual genes or small genomic segments, may collectively contribute to the expansion of duplicated genes, thus to the restructuring of metabolic networks. In human, 30%-52% of gene duplication events arise from SSDs [22],

comprising 48% of all human protein coding genes [23]. Tandem duplicates, one type of SSDs, account for 16% and 14% of Arabidopsis and rice genes, respectively [24]. SSDs were considered responsible for the expansion of gene families involved in response to environmental stimuli, such as immune-related families (human), disease-resistance genes (NBS-LRR) [25], and receptor-like kinases [26]. Indeed, their more or less continuous occurrence may make SSDs better suited than (infrequent and episodic) WGDs to provide raw material for a genome to evolve environmental adaptations. For example, the evolution of C4 photosynthesis in cereals largely involved SSDs, although the entire required gene set had been duplicated previously in a WGD with most of the genes subsequently lost.

Following duplication, gene pairs experience one of three general fates

Most gene functional groups show post-duplication gene preservation/loss rates that are indistinguishable from the genome-wide average. Such 'neutral' loss of duplicated genes presumably involves mutations that were not strongly selected against thus were able to accumulate and eventually inactivate the genes [27], closely resembling the 'nonfunctionalization' described [e.g. [28]] as the fate of the vast majority of duplicated genes. Population genetic models suggest that loss of most duplicated genes may happen during the first few million years following duplication [29]. Intrinsic or extrinsic factors may influence gene retention rates. Duplicated genes are presumably identical at 'birth' (duplication), however in a newly polyploid nucleus they may have as much as several million years of independent evolution (allopolyploidy), and one copy usually has a higher probability of loss than the other. For example, different yeast species lose the corresponding copy of their shared single copy genes in most cases [30]. Homeologous chromosomes may be epigenetically 'marked', and lose

genes (or mutate) at different rates [31]. Losses of chromosomes or large segments could result in gene loss that is largely if not wholly independent of gene function.

Genes in some specific functional categories duplicate and reduplicate. Several gene functional groups are preferentially preserved in duplicate [32-37]. Coding regions of genes preserved in duplicate tend to be functionally complex [32], under purifying selection [28, 32], and evolve in concert [38, 39], with tendencies to retain duplicate genes involved in signal transduction and transcription, and lose DNA repair genes [34, 35]. Pfam domain-based groupings reveal heterogeneity in the broad GO categories used in many studies for analysis of gene retention/loss patterns, for example showing one abundant protein-protein interaction domain (LRR) to be usually preserved in duplicate while two less-abundant domains (SET, TPR) are usually restored to singleton state [40]. Regulatory divergence between members of preserved gene pairs may contribute much to morphological complexity [41], perhaps offering important benefits to polyploidized lineages [42]. Classical ideas about one gene copy diverging to new function [neofunctionalization [43, 44]] have more recently been tempered by findings that many duplicated genes may subdivide ancestral functions [subfunctionalization [45]]. Subfunctionalization may be a stepping-stone to neofunctionalization [46]. Retention of some duplicated genes may be an indirect consequence of the fate(s) of nearby genes. In human, for example, pre-existing fixed duplicates may facilitate the fixation of neighboring duplicates [47], resulting in less than average copy number variation for genes adjacent to WGD-duplicates [48].

Other specific genes and gene functional groups show more extensive loss of duplicate copies than the genome-wide average. Duplicated gene loss may not be ‘neutral’ when increased dosage of gene products reduces fitness, such as in defense reactions [49, 50] and stress responses [51, 52], or when genes in dosage balance with each other are not duplicated at the

same time (in the case of SSDs) [53]. Accordingly, some gene functional groups are preserved in duplicate significantly less frequently than the genome-wide average. This observation alone might be viewed as noise – among thousands of functional groups, some must incur more gene loss than others due to random factors. However, the gene functional groups that have incurred greatest loss of duplicated copies are closely correlated following independent duplications in Arabidopsis and rice that are separated by more than 100 million years of evolution, at statistical probabilities that essentially rule out false positives [37]. Multiple genome alignments likewise show some individual genes to have been repeatedly restored to single-copy status following many different genome duplications in independent angiosperm lineages [36, 54]. Repeated restoration of certain genes to singleton status at a greater-than random frequency suggests that an underlying set of principles of molecular evolution may contribute to the fates of gene and genome duplications [37].

Functional importance of single copy vs. duplicated genes

The functional importance of genes can be measured through different approaches, perhaps the most direct one being to evaluate the phenotypic effect caused by rendering a gene nonfunctional. Traditionally, one would think that single copy genes are more prone than duplicated genes to revealing 'knockout' (KO) phenotypes because of a lack of genetic redundancy. KOs of duplicated genes may be masked at least somewhat by one another and less likely to reveal a phenotype, reasoning that is generally supported by large-scale KO mutant screens in yeast [55] and nematode [56]. However, most, if not all, duplicated genes experience DNA sequence divergence over time [57], presumably eroding their ability to provide functional compensation for one another.

Indeed, the ability of duplicate genes to functionally compensate for each other is highly variable among different species [58]. In mouse, 'essential' genes, defined as those for which deletion causes lethality or sterility, occur in proportions that are not significantly different in duplicates versus singletons, based on a sample of genes with phenotypic data [59, 60]. With more data collected from individual experiments, mouse KO mutants for duplicated genes may prove more likely to be lethal than those for single copy genes [58].

Though a number of large-scale mutant screens have been done in Arabidopsis, few have addressed the relationship between phenotypes and gene duplication level. Analysis of phenotypic data from 3871 Arabidopsis KO mutants with transposon or T-DNA insertions plus 1489 published KO phenotypes, found KOs to cause a significantly lower proportion of phenotypic changes in duplicated genes than single copy genes [61]. In another study of 2400 published KO phenotypes, no significant difference was found in the proportions of phenotypes among unique genes, somewhat redundant genes, and highly redundant genes, grouped according to Blastp results [4].

While literature surveys may be inherently biased (with genes showing no KO phenotype perhaps reported less frequently), Hanada et al. [61] found no significant difference between de novo and published evidence. Further, as discussed by Hanada et al [61], the percentage and severity of gene KO phenotypes are related to the sequence divergence of duplicated genes, indicating that duplicated genes could be divided into subgroups with distinct likelihoods of finding phenotypes.

Single copy genes are not a homogenous population

While a broad generalization seems intuitive that single copy genes are more prone to show KO phenotypes than duplicated genes, a variety of subgroups of single copy genes can be

distinguished, for example, lineage-specific singletons (LSSs) and duplication-resistant (DR) genes.

LSSs are defined as genes that have no homolog identified in other species. Though LSSs receive little attention in the literature, they constitute a majority of lineage-specific genes (LSGs) [62]. LSGs have received more attention, and for example are believed to be fast-evolving as indicated by significantly more SNP alleles and higher non-synonymous to synonymous mutation ratios in Arabidopsis [62]. Other characteristics of LSGs include short protein length [63-65], fewer than average exons [62, 63], lack of functional annotation [62, 63], low expression level, limited expression breadth, and stress-related expression patterns [66]. Arabidopsis LSGs with annotation are enriched in secretory proteins [62, 63] and mitochondrion-targeting proteins [62], and are underrepresented in chloroplast-targeting genes. Their expression patterns [64] along with the GO terms of their co-expressed genes [62] associate LSGs with reproduction-related functions and stress-response.

Species specific WGDs, different evolutionary rates and functional divergence might reasonably be expected to impart variation among different plant species in the copy numbers of conserved genes [67]. The distinguishing characteristic of DR genes is that they have little variation in copy number across taxa, being single copy in most plant species [67]. While different DR lists have been published by different research groups based on various criteria, some of their characteristics are remarkably consistent, including more exons/introns than average genes [63, 68], conservation in metazoans [63, 69], a higher than average proportion of plastid-targeting genes and genes functioning in DNA/RNA metabolism [68, 69], and increased purifying selection [63, 69].

RESULTS

Classification of Arabidopsis single copy genes

The number of Arabidopsis single copy genes, as determined by different approaches, varies from 2570 [63] to over 14993 [69] including estimates of 4863 [70], 5460 [68], 5980 [71] and 8499 [4] , each with its own advantage for a particular study. Yet, common features were observed for LSGs (most being LSSs) and DR genes among independent studies [62-65] [68, 69], despite the difference in gene lists. Both being single copy in Arabidopsis, LSSs and DR genes were distinguished by their copy numbers in other plant species, which could serve as a parameter to divide Arabidopsis single copy genes into different groups.

Here we define as single copy those genes that have no non-self blastp hit in the same genome with e-value less than or equal to 1e-10. By this criterion, there are 4136 single copy genes in Arabidopsis, near the low end of the range of other estimates [68, 70, 71]. To determine the copy number of homologs in other species, we considered a relatively slowly evolving monocot genome (Oryza) [72], a eurosid outgroup thought to resemble the ancestral eudicot genome (Vitis)[6, 67], and eudicot genomes with and without recent WGD (Eurosid Ⅰ and Eurosid Ⅱ)(Populus [7] and Carica [73], respectively) [74].

Based on the copy number of their homologs in other species, Arabidopsis single copy genes can be divided into LSSs, with no homologs in all four species; and conserved singletons, with one or more homolog(s) in at least one species. Further, conserved singletons can be divided into DR genes, with only single copy homologs in all four species; singletons with their homologs duplicated in all four species (SD); and others (OT), including singletons remaining fully conserved (OT-F, with homolog(s) in every species) and partly conserved (OT-P, having homolog(s) in at least one other but not all four species) (Table 2.1).

To compare the general features of our singletons to others reported, the GO percentage (=the number of genes with certain GO term/total number of genes) was calculated and compared between each subset and the whole genome (Table S2.1, S2.2). The enrichment of DR genes in DNA or RNA metabolism, plastid and chloroplast as well as the overrepresentation of LSS genes in mitochondrion and unknown proteins (unknown biological processes/molecular functions/cellular components; Table S2.2), were generally consistent with prior reports [68, 69].

The likelihood of showing knockout phenotypes is different among subsets of singletons

To investigate levels and patterns of functional importance among different subsets of single copy genes, we assessed the percentage of KO mutants showing a phenotype in each subset, using three datasets that included a wide range of phenotypes. Two datasets [4, 61] introduced under the section "Functional importance of Single copy vs. Duplicated genes" were utilized. For Hanada et al.'s dataset [61], only the 3871 genes with KO mutants were used in the following analysis, because the 1489 genes with published phenotypes were redundant with Lloyd and Meinke's dataset [4]. In addition, we included Kuromori et al's screen of 4000 DS-insertional mutants [75], containing 3800 genes.

The statistic that we adopted for comparing the likelihood of knockout phenotypes in different gene subsets is 'phenotype percentage' (PP), calculated as the number of genes in a group for which knockout mutants show discernible phenotypes, divided by the total number of sampled genes in the group. For example, in the 4000DS dataset [75], there are 46 DR genes, of which 2 showed mutant phenotypes, thus the phenotype percentage is 4.35% (2/46) (Table S2.3). In the Lloyd and Meinke dataset [4], containing only 2400 phenotypes/genes without any background mutant population, all the genes in each subset are considered 'sampled genes', as it is a genome-wide collection of phenotype data. For example, the phenotype percentage for the

DR subset in Lloyd and Meinke's dataset is 12%, with 49 DR knockouts showing phenotypes among 409 sampled (Table S2.3).

Datasets composed of previously published phenotypes, such as Lloyd and Meinke, tend to have a higher PP, because they incorporate efforts from multiple experiments by a number of research groups, increasing the chance of phenotype discovery. For example, the PP of 4000DS (3%) is lower than those of the other two data sets (6.5% for Hanada, 9% for Lloyd and Meinke), though within the range of results for other Arabidopsis studies [76]. Moreover, there may be a bias in favor of mutants showing phenotypes being published more frequently than those that lack phenotypes.

The overall pattern of PPs among the four subsets of Arabidopsis single-copy genes is similar in the three datasets (Figure 2.1), except for SD in 4000DS: on average (Table S2.3), SD [singletons with their homologs duplicated in four other species] has the highest PP (16.1%), DR shows slightly lower (8.6%) but similar PP to OT (10.6%), and LSS has the lowest PP (0.1%).

SD stands out with the highest average PP, having the highest PP in Hanada and Lloyd and Meinke datasets but not in 4000DS. Only 7 SDs are in the 4000DS population, and none showed a phenotype. However, three have phenotypes in the other two datasets, indicating that the low PP for SD in 4000DS may be partly due to the quality of the mutants (e.g., genes are not entirely knocked out) rather than the small sample size.

LSS also stands out, having the lowest PP across all datasets. LSSs are suspected to have lineage specific functions that are not identified yet, or involved in stress responses (above). Therefore, their low PP could reflect phenotypes that are too subtle to be easily detected, or failure to assess the conditions under which their phenotypes are expressed. LSSs show a striking deficiency of KO mutants, with less than 50% having available homozygous mutants in the

SALK collection of homozygous KO lines (http://signal.salk.edu/cgi-bin/homozygotes.cgi), versus more than 80% for the other three subsets (Figure S2.1). This raises the tantalizing hypothesis that some LSS genes are 'essential', rendering homozygous KO plants inviable.

It was somewhat unexpected that DR genes had phenotype percentages slightly lower than the overall averages for OT and much lower than that of OT-F (Table S2.3). This seems to suggest that copy number regulation (or lack thereof) in other species does not predict the likelihood of finding a KO phenotype in Arabidopsis.

The proportions of essential genes differ among subsets of singletons

In addition to presence/absence, severity of a phenotype is another criterion in evaluating gene importance. Most studies in other organisms (bacteria, yeast, fruit fly, mouse and others) use the proportion of essential genes, i.e. for which KO is lethal or sterile, as a measure of importance for a group of genes [58]. However, in Arabidopsis, most large scale mutant screens have not looked for lethality, as it is not obvious (e.g., requiring silique or seed check through microscopes [77, 78]; or segregation ratio analysis [79]). The absence of homozygous knockout mutants is an indicator of essentiality of genes, but further confirmation is required to rule out alternative reasons.

No lethal phenotype was reported in the 4000DS dataset. The "seed" Category of Hanada et al [61] includes embryo-defective mutants, one major subgroup of lethal mutants, yet these are not separated from other seed phenotypes in this dataset. The Lloyd and Meinke dataset makes lethal phenotypes a discrete category, showing the proportion of essential genes to be distributed similarly to the overall phenotype percentage among the four subsets (Figure 2.2).

Vegetative, reproductive and seed phenotype percentages varied among datasets but were similar to overall phenotype percentages among the four subsets of single copy genes

Phenotypes can be grouped in different ways. For example, there are eight major phenotype groups (seedling, leaves, flowering and growth, stems, branching, flowers (morphology) siliques, seed yield) in the 4000DS dataset, three (Vegetative, reproductive, seed) in Hanada's dataset, and four (essential, morphological, cellular and biochemical, conditional) in Lloyd and Meinke's dataset.

The PPs of particular gene groups may shed light on function as well as functional importance of the underlying genes. For example, a group of genes with most KO phenotypes being seed defective might tend to function in seed development, and may be viewed as more important than a group consisting mainly of leaf phenotypes [61].

For comparison among the three datasets, phenotypes were regrouped according to Hanada et al. [61], the one with the fewest groups (Table 2.2). During regrouping, the main groups of phenotypes in each dataset were not broken into more detailed subsets. While some discrepancies remain in the contents of phenotype groups, several common features are clear.
DRs and OTs have similar PPs in most cases. The exception is again the 4000DS dataset, in which most DR phenotypes are contributed by "seed", while a high portion of OT phenotypes belong to "vegetative" (Figure 2.3). This might imply that DR KO mutant phenotypes are somehow more serious than OT mutants. However, such a conclusion is constrained by limited phenotypic data.

The variation of SD PP among different datasets is the largest in each phenotypic category (Figure 2.3, Figure S2.2). Two SD mutants with vegetative phenotypes in the Hanada dataset also have phenotypes in the Lloyd and Meinke dataset, but one of them became "seed".

Though one gene having multiple phenotype categories is not rare [4, 75], “seed” in Lloyd and Meinke’s dataset corresponds to lethal phenotypes caused by defective embryo/seed, leaving no viable seedling to show any vegetative phenotype. Such conflicting phenotype data might be caused by the lack of confirmation, for example, via complementation test, different mutant allele(s), and gene product measurement. Despite the variations, the SD group still holds the highest PP in at least one dataset in “Seed” and “Vegetative”. In contrast, no reproductive phenotype is found in SD.

Low reproductive PP is a common phenomenon for other subsets and among datasets (Figure 2.3), and even for a much earlier summary of Arabidopsis phenotypes [80]. A possible cause is that most gametophytic defects are lethal and thus are classified as “essential” instead of “reproductive” [4]. Compared to vegetative phenotypes, reproductive phenotypes are considered more severe because of their direct effect on the next generation [61]. The survival of a lineage may depend in part on having only some minimal number of genes for which deletion confers a severe defect. The abundance of “seed” phenotypes, arguably the most severe among the three categories, could possibly be explained by multiple screens targeting them as part of a long-term endeavor to identify all essential genes [78, 81].

As noted above, the PPs of LSSs were still the lowest in all comparisons. LSS phenotypes are only found in Lloyd and Meinke’s dataset. There are three vegetative phenotypes and one seed phenotype for LSS, following the general trend that vegetative phenotypes are the most abundant.

In summary, the PP patterns in these specific phenotype groups resemble those of all phenotypes and lethal phenotypes (above), tending to be lowest in LSS, highest in SD, and

similar between OT and DR classes. Therefore, it seems that such patterns are not caused by the over- or under-representation of a specific type of phenotype in a certain subset.

Though the three datasets studied here have phenotype data for useful numbers of genes in each subset, there are still many genes completely uninvestigated. Among those with their mutants studied, some were merely screened for visually-evident morphology alternations, while others were additionally scrutinized for non-obvious phenotypes such as cellular level abnormalities. Therefore, the absence of KO phenotypes in many cases may be for reasons unrelated to gene function: KO lines might never be assessed under a certain condition or using a particular method. Moreover, the inconsistency in phenotype data among different datasets reflects the problem of mutant quality: phenotypes from different mutants for one gene might be different or even conflicting (eg. lethal or non-lethal), indicating that not all mutants were real knockouts. Collectively, if the scientific community would like to further investigate these subsets of Arabidopsis single copy genes, more needs to be done to improve and expand the phenotype data.

DISCUSSION

Similarly to duplicated genes, single copy genes are a diverse group. Their characteristics can be related to their conservation level as well as the copy number of their homologs in other plant species, according to which we divided Arabidopsis single copy genes into four subsets: LSS, OT, DR, and SD. For subsets DR and LSS, their descriptors (protein size, gene structure, expression pattern and others) have been investigated in detail in other studies. Yet, phenotypes, which are most directly related to gene function, have not previously been summarized and compared among those subsets. We compared phenotype datasets for Arabidopsis gene knockout

mutants to investigate the proportion of genes with phenotypes (phenotype percentage--PP) in each subset.

Despite differences in the three Arabidopsis phenotype datasets with regard to the numbers of genes and phenotypes, it remains an accurate generalization that the conserved groups (OT, DR, SD) carry more important functions than the non-conserved group (LSS), as reflected by higher proportions of knockout mutant phenotypes as well as essential genes. This is consistent with findings in bacteria [82], yeast [83][84] and mouse [60]. Further, the PP is positively correlated with the number of species the genes are conserved in (Figure S2.3), using the most up-to-date Lloyd and Meinke dataset. A gene preserved across long evolutionary time (i.e., in many species) is likely to function in fundamental metabolic processes such as protein synthesis or DNA replication. The disturbance of these processes, through removing such genes from a genome, usually has negative consequences [85].

The most consistent results are found for LSSs, in which the phenotype percentage is consistently low, with only 6 (0.4%) published phenotypes for the 1669 genes through 2012. In contrast to conserved genes, LSSs are most simply explained by recent origin, and thus have not been 'tested' by natural selection over long evolutionary times. An alternate, less parsimonious hypothesis is that LSSs have not survived the test of time, and have been eliminated from most lineages. The lack of phenotypes for their knockout mutants in all three datasets implies that they may not have important functions. Yet, the lack of HM SALK lines (Figure S2.1) compared to other subsets suggests that they might have essential functions. A systematic effort to isolate HM mutants for those without HM SALK lines would test whether this possibility is true. It is also worth investigating whether LSSs frequently have conditional phenotypes, given their possible role in stress response (section "Single copy genes are not a homogenous population").

OT is the largest subset of the four classes of single copy genes, containing 2011 (48.6% of) genes , and can be further divided into ‘partly’ (790) and ‘fully’ conserved single copy genes (1221, without DR and SD). The PP is much higher in fully-conserved (13.5%) than partly-conserved OTs (4.8%) (Table S2.3), making fully-conserved OTs the main contributor to the high PP of OT. This group represents single copy genes with reasonable copy number variation among their homologs.

SD is one extreme subgroup of fully conserved single copy genes, with duplicated homologs in all four plant species, making them a small yet unique population. With high PP and high proportions of annotated function in almost every category (Table S2.1), SD involves relatively well-known genes that are duplicated in many taxa but not in Arabidopsis. The retention of multiple gene copies in many other taxa implies either subfunctionalization or some advantage of multiple gene doses, with the single Arabidopsis copy perhaps being more prone than an average gene to show a KO phenotype. To confirm this assumption, functional analysis of their homologs in other plant species is necessary.

Particularly perplexing are the DR class of fully conserved genes, with little copy number variation. The DR class has lower average PP (8.6%) than other fully conserved single copy genes (13.5%) in the three datasets (Table S2.3). The fact that following many independent genome duplications these genes are recurrently restored to low copy number but not lost [37], seems to imply that they serve some important function(s). Increased knowledge of the functions of DR genes would shed light on the underlying mechanisms that favor their repeated return to single-copy status after duplication.

CHAPTER 3

PHENOME ANALYSIS OF DUPLICATION-RESISTANT GENES USING ARABIDOPSIS T-DNA INSERTIONAL MUTANTS

Chengbo Zhou, Kenneth Feldmann, Kathryn Millward and Andrew H. Paterson. To be submitted to Physiologia Plantarum.

ABSTRACT

Genes conserved among multiple plant species are expected to have basic and important functions, thus being a vital component of plant genomes. Among conserved plant genes, 'duplication-resistant' (DR) genes stand out because of their strong tendency to return to single-copy dosage despite recurrent, independent duplication events. Their dosage sensitivity strongly suggests that DR genes experience different selective constraints than other conserved genes. The recurring removal of duplicated gene copies is a rare and as yet not-well-explained fate of gene duplication. This fate shows non-random association with gene function, as implied by enriched GO terms in DR genes, making functional study of DR genes a path by which to decipher the basis of duplication resistance. In this study, we assessed Arabidopsis DR genes' function via their knockout phenotypes. T-DNA insertional mutants of 179 DR genes and 64 non-DR singletons were screened for root and stress-triggered phenotypes. Compared to single-copy-random (SCR) genes, most with duplicated homologs in other plant species, T-DNA insertional mutants of DR genes were less likely to exhibit phenotypes than SCR genes under all tested stress conditions except salt. The overrepresentation of salt phenotypes, together with underrepresentation of ABA and cold sensitive phenotypes in the DR group were also seen in comparison with other non-DR singletons (nDR), which had been early DR candidates later found to be non-DR by analysis of more genomes. On the other hand, severe phenotypes, including visible seedling alternations as well as phenotypes indicative of homozygous lethality, occurred more frequently in the DR group than the controls. Distinctive phenotypic features of DR genes may provide further information toward learning the selective constraints that repeatedly return these genes to single-copy dosage. The phenotypes discovered and mutants characterized herein, serve as a foundation for in-depth functional study. Better understanding of

DR genes' function would contribute greatly to plant functional genomic analysis, and provide insight into the evolutionary basis of their persistent single copy status.

ABBREVIATIONS

WGD (whole genome duplication); HM (homozygous); HT (heterozygous); WT (wildtype); PP (phenotype percentage)

INTRODUCTION

The evolutionary history of plant genomes is characterized by often-recurrent whole genome duplications (WGDs) as well as numerous small-scale duplications of individual genes or small genomic regions (SSDs) [1, 2]. In angiosperms, the original set of genes in the last universal common ancestor (LUCA) has been at least duplicated (without exception) and re-duplicated in most species. Most duplicated gene copies were either non-functionalized due to accumulated mutations [3], or became new genes without recognizable sequence resemblance to the original copy [3]. In either case, these once-duplicated genes reverted to single copy dosage. In contrast, multiple copies were retained for a minority of genes, forming gene families of various sizes.

Due to diverse processes and some random factors, the copy numbers of conserved genes varies among species. Yet, there exist appreciable numbers of genes that are widely conserved only in single copies or low copy numbers. These genes serve as valuable markers for phylogenic study [4, 5]. Moreover, their recurring return to low copy number following recurring duplication events, which has been shown to be non-random [6], may be meaningful for fitness of a genotype, though the underlying selective mechanisms remain unclear.

Genes with persistent single copy status have been assessed by several research groups [4, 7, 8]. The names given to these genes vary, thus to avoid confusion, they are referred to

herein as ‘duplication-resistant (DR) genes’. The lists of DR candidates identified by each research group differ from one another, due to the study of different species and use of different analytical methods. Nevertheless, much congruence was found in their characteristics. The number of DR genes is much higher than expected under the assumption of random loss, indicating that selective forces contribute to their single copy status. Indeed, purifying selection acting on these genes is implied by evidence including low dN/dS rates [7] and low Ka values [8]. Moreover, DR genes are structurally complex [4, 7], containing greater than average numbers of exons/introns; and functionally biased, being over-represented in GO terms such as DNA or RNA metabolism, chloroplast and plastid [4, 8].

Insights into causes of ‘duplication resistance’ (copy number regulation) have been inspired by functional features of DR genes. For example, enrichment for chloroplast-located DR proteins raised the hypothesis that dosage balance between these DR proteins and chloroplast-genome-encoded interaction partners would be disturbed by nuclear but not chloroplast genome duplication, resulting in selection against unilateral duplication [2]. Reasonable as it is, the theory is limited to a small subset of DR genes. Duplication resistance of genes encoding subunits of macromolecular complexes, for example, is not well explained by the dosage balance hypothesis [9], according to which these genes should be WGD duplicates instead of persistent singletons [2]. In this case, it may not be increased dosage that causes trouble, but rather mutated proteins produced by one of the duplicated copies that compete with the wild type protein in binding to other components, and form inactive complexes [8]. Experimental confirmation of hypotheses about causes of duplication resistance would be valuable, and motivates functional study in deciphering DR genes’ copy number syndromes.

More definitive than predicted functions is empirical observation of phenotypic changes resulting from silencing a gene, directly reflecting its function. For example, a plant lacking proteins functioning in a critical metabolic pathway may experience premature death, while the absence of enzymes involved in pigment synthesis may merely change color intensity or pattern. Therefore, to study gene function, mutants with disturbance of few, preferably one, gene(s) per line were made and their phenotypes searched [10].

Arabidopsis mutant resources [10-14] and their phenotypic descriptions [15-17] are abundant, and from the published knockout (KO) phenotypes some phenotypic features of DR genes were extracted (Chapter 2). Compared to other fully conserved singletons (OT-F), Arabidopsis DR genes were less likely to either reveal knockout phenotypes or be essential, indicating that functions carried by DR genes might not be as important as those of OT-F genes (Chapter 2). The relatively low phenotype percentage (PP) of DR genes was seen in all three phenotype categories, namely, Seed, Vegetative and Reproductive (Chapter 2). The results suggest that duplication resistance might not be directly related to functional importance, nor correlated with a particular phenotype category. However, these observations may change with new phenotype data, especially given that as many as 88% (360/409) of DR genes lacked reported knockout phenotypes (Chapter 2). Among those without phenotypes are genes whose mutants have not been investigated, implying the possibility of uncovering new phenotypes.

The potential for phenotype discovery is particularly large in conditional phenotypes, which require a specific environment to discern, because of the vast range of conditions that plants must adapt to in nature. For example, different concentrations of salt as well as a variety of measurements (germination rate, root length, leaf numbers and others) could be applied in a salt screen. Environmental conditions affecting crop production have been of continuing interest,

including drought [18], salinity [19], and cold [20]. Candidate genes conferring stress tolerance have been important targets for development of molecular tools for crop improvement [21]. Though numerous stress screens involving thousands of genes have been performed in Arabidopsis [22-27], none have focused on DR genes, implying that many DR mutants have not been tested under stress yet.

In this study, T-DNA insertional mutants (SALK lines) [10] of Arabidopsis DR genes, and non-DR but conserved singletons as the control group, were assessed in a variety of phenotype screens, focusing on four stress conditions that sought to emulate major stresses threatening crop productivity, including drought (ABA, mannitol), salt, cold and heat, and high sucrose condition. The original DR candidates include those defined in Chapter 2, as well as conserved single copy genes (between Arabidopsis and Rice) with DR domains, while the original control group (SCR) contains mostly SD and OT-F genes. Later adjustment (detailed in methods) resulted in re-classifying some genes from the DR group to the 'nDR' control group. The final sample was limited to qualified DR candidates with available SALK lines, preferably with insertions in exons or introns. The five stresses were chosen because they were relatively well studied [28-32], thus easier to connect DR function with known stress response pathways or networks. Together with the highly conserved nature of the test genes, knowledge gained through this study may contribute to molecular breeding of stress-tolerant crops.

In addition to stress-response candidates, root length of mutants compared to wildtype (WT) Col0 plants was scored on vertical plates. Though not intentionally screened, abnormal seedlings were noted for plants grown in growth chambers and referred to as soil growth phenotypes. Phenotypes indicating lethality for lines that lacked homozygous (HM) plants for T-DNA insertion, such as dying seedlings and abnormal seeds in HT siliques, were classified as

potentially lethal (PL) phenotypes. Together, these phenotypes exhibited a relatively complete picture of the outcome of DR genes' knockout. Through comparing the phenotype data between DR genes and other singletons, phenotypic features that may be associated with duplication resistance were identified.

MATERIALS AND METHODS

DR, SCR and nDR gene lists

Arabidopsis genes were blasted against one another as well as those of four other plant genomes (*Carica papaya, Populus trichocarpa, Vitis vinifera, and Oryza sativa*). Genes with exactly one blastp hit (e value less than or equal to 1e-10) in all five plant genomes were considered DR candidates, forming one DR subgroup named 'strict singleton (SS)', which was further divided into non-syntenic and syntenic classes according to gene location [33, 34]. The other subgroup, 'protein domain (PD)', contains genes conserved as single copy in both Arabidopsis and Oryza and with protein functional (Pfam) domains that are significantly enriched in singletons [6].

Copy numbers of the DR candidates in 21 genomes (*Manihot esculenta, Ricinus communis, Populus trichocarpa, Medicago truncatula, Glycine max, Cucumis sativus, Prunus persica, Arabidopsis thaliana|Arabidopsis lyrata, Carica papaya, Citrus sinensis|Citrus clementina, Eucalyptus grandis, Vitis vinifera, Mimulus guttatus, Aquilegia coerulea, Sorghum bicolor|Setaria italica|Oryza sativa|Brachypodium distachyon, Zea mays*) were assessed on Phytozome 7.0. To reduce redundancy and make the dataset easier to analyze, multiple counts were 'collapsed' into a single count for species that experienced the same sets of WGDs or whole genome triplications (WGTs). Particularly, average counts were taken for two arabidopsis, four diploid grass, and two citrus species, with the only exception that the count cannot be zero

as long as one lineage is nonzero. For example, if the count was '1' in *Arabidopsis thaliana* and '0' in *Arabidopsis lyrata*, the collapsed count would be '1' which assumes that *A. lyrata* contains incomplete data. After this collapse, 16 lineages remain. DR candidates without homologs in two or more genomes were dropped from the initial list, and were named 'nDR', while the remaining 303 genes were considered DR candidates (Table S3.1).

Other Arabidopsis singletons, which were not single copy in at least one of the other four species, were named SCR (single copy random) genes, as their variable single copy status suggested random factors [2]. The original control group (SCR) contained 24 randomly selected Arabidopsis single copy genes conserved in all four other species ('SD' or 'OT-F' in Chapter 2), and three Arabidopsis single copy genes conserved in at least one but not all four other species ('OT-P' in Chapter 2) (Table S3.1).

Genotyping

Seeds ordered from Arabidopsis Biological Resource Center (ABRC) were sown on soil in sets of six, from which a pooled leaf sample was collected for DNA extraction. Plant genome DNA was extracted by cetyltrimethylammonium bromide (CTAB)-based Method [35] with modifications.

PCR was done on the pooled sample for each mutant line. Primers were found on http://signal.salk.edu/tdnaprimers.2.html, where the genotype scoring method could be found. Instead of conducting the standard protocol, which in our case often resulted in nonspecific amplification, two PCR reactions were done with the primer combination (LP+RP) and (LB+RP) (http://signal.salk.edu/tdnaprimers.2.html), respectively. The genotypes corresponding to different banding patterns were shown in Figure M3.1, with WT standing for 'wildtype', HM representing 'homozygous' and HT for 'heterozygous' for the T-DNA insertion.

Seeds harvested from homozygous (HM) plants, with identical T-DNA insertion in both alleles of the target gene, were directly used in phenotype screens. For heterozygous (HT) samples, with one knockout allele and one functional allele of the target gene, 12 seeds were planted and the resulting seedlings were genotyped to seek one or more HM plant(s), from which homozygous (selfed) seeds were collected for phenotype screens.

Lethality test

For lines lacking HM plants, young fruits of HT parents (if available) were assayed under a dissecting microscope to identify abnormally developed seeds.

Planting

Soil was put into pots sitting in flats and totally saturated with water before planting, with 2-3 cm water remaining in the flat. Once the seeds were put in pots, each flat was covered with a transparent plastic lid, and kept at 4o C for 3 days to reduce dormancy and improve synchrony of germination. After moving the flats to a growth chamber (22°C, 16:8 light: dark cycle, 100µ Einsteins), the lid was kept on for several days. After removing the lids, flats were bottom watered when the soil became noticeably dry.

Stress screens, root screens and Kanamycin test

Stress screens include those involving exposure to ABA, mannitol, cold growth, cold germination, heat, heat recovery, salt and sucrose. These were done on petri dishes with specific media. All media contained exogenous sucrose (5g/L) except for that used in the sucrose screen. The basic medium used for root, etiolation, cold, heat and Kanamycin (20mg/L and 50mg/L) screens was 0.5xMS (Murashige and Skoog [36]). The basic medium used for mannitol (375mM), ABA (1.5µM), sucrose (300mM) and salt (125mM) was 1xMS. Both ABA and

mannitol media were supplemented with MES (2-(N-morpholino)ethanesulfonic acid) hydrate (5g/L), which serves as a buffer to stabilize pH.

Seed Sterilization

Seeds used in stress, root and kanamycin screens were sterilized by a mix of clorox and water (volume 1:1) with 2 drops of Triton X-100 per 100 ml solution. In a 1.5ml Eppendorf tube, seeds were mixed well with the clorox solution and submerged for 8 minutes, then rinsed with 1.5 ml sterile water three times. Sterile water (1ml) was added after the rinses to enable planting seeds on the plates with a pipette. Soft agar (0.1%) was added instead if the seeds needed to be stored (at 4°C) for more than three days.

Plate arrangement

ABA, mannitol, sucrose, salt, cold growth, heat/heat recovery screens: For each mutant line and controls (Col0), 10-15 seeds were plated evenly in a straight line parallel to one side of a square plate (15 x 100 x 100mm). Six to eight lines (that may include the WT) were screened per plate (Figure M3.2).

Root screens: For each mutant line as well as the control (Col0), 10-15 seeds were plated evenly in a straight line parallel to one side of a square plate (15 x 100 x 100mm). The seeds were about 1 cm from the top of the plate when the plate was positioned vertically. Two mutant lines were plated side by side, each taking one half of the plate's side length (Figure M3.2).

Cold germination screen: Square plates (15 x 100 x 100mm) with 6x6 grids on the bottoms were used. On each plate, seeds from two replicates of 17 mutant lines as well as controls were plated randomly, with each replicate occupying one grid. While plating, one drop of seed suspension was placed in each grid, containing 20-30 seeds.

Heat/Heat recovery and cold growth screens (early trials): Some of the earliest screens were done on round plates (100 x 15 mm). Three mutant lines or two mutant lines with one control were screened per plate, each occupying a 120 degree sector, where 20-30 seeds were plated evenly (Figure M3.3).

Kanamycin screens: Four lines (or seeds from four individual plants) were inoculated per plate, each taking ¼ of the plate area. Around 20~30 seeds were plated evenly for each line (or individual plant) (Figure M3.3).

Phenotyping

If not noted otherwise below, plates were first photographed at the 14th day after plating, and again every week for 2~4 weeks; growth conditions were 22°C, 100 µEinsteins light intensity, 16:8 hour light: dark cycle.

After plating seeds, ABA and sucrose plates were photographed at the 7th day; Root plates were placed at 4o C for 3 days before being kept vertical in a growth chamber; Cold germination plates were put in a 10o C growth chamber; Cold growth plates were put in a 22°C growth chamber for 7 days before transfer to a 10°C growth chamber; Heat plates were wrapped with vent tape instead of parafilm (which would melt at 34°C) and put into a 34°C growth chamber; Heat recovery plates stayed at 34°C for 7 days before being transferred to a 22°C growth chamber, where they were photographed after 7 days; Kanamycin scoring started at the 10th~12th day in a 22°C growth chamber, and scores were directly recorded in a notebook (not photographed).

Phenotype scoring

Phenotype scoring was done using photos of the plates for all screens except Kanamycin. One score was assigned to each mutant line per plate, based on the average performance of 10-30

individuals in that mutant line compared to the control. In most cases, the score is an integer ranging from 0 to 5, with 0 representing ‘no germination’, 1 for ‘very sensitive’, 2 for ‘somewhat sensitive’, 3 for ‘normal’ (similar to wild type), 4 for ‘somewhat tolerant’, and 5 for ‘very tolerant’. Sensitive mutants are smaller than the control while tolerant mutants are bigger (Figure M3.4). For a few cases in which the most striking difference was color, yellow was considered to be ‘sensitive’ while ‘green’ was ‘tolerant’. When only a few (<50%) individuals within a mutant line showed phenotypes, the score ‘seg’ (for segregating) was assigned (Figure M3.4).

In addition to depicting the performance of seedlings, root scores mainly represented root length, with 1 being ‘short’, 2 being ‘slightly short’, 3 being normal, 4 being ‘slightly long’, and 5 being ‘long’ (Figure M3.5). The 0 still stands for ‘no germination’ and ‘seg’ means only a few plants within a mutant line showed a phenotype.

The average of all non-seg scores of a particular mutant was calculated per trial, representing the overall performance during the 2-4 week growth period. If there was only one non-seg score, it would be recorded as ‘single read’ instead of a number. The ‘single read’ was not considered a valid phenotypic score if no other trial was done on this mutant or no other score was assigned because it raised the possibility of various artifactual outcomes, for example, that the plate was contaminated. For a final score of one trial, mutants with average scores from 2.5-3.5 were re-assigned with score 3; mutants with average scores lower than 2.5 were re-assigned with 1 (if there was no 3) or 2 (if there was one 3); those with average scores higher than 3.5 were re-assigned with 5 (no 3) or 4 (one 3) (Figure M3.6).

Trial scores were combined together to create a final score. Similar scores were interpreted as an increase in the level of confidence with which sensitivity or tolerance was

inferred. For example, if a mutant was assigned score 2 in both trials, then the final score would be 1. In contrast, divergent scores were interpreted as a decrease in the level of confidence with which sensitivity or tolerance was inferred. For example, if a mutant was 1 in one trial and 3 in the other, the final score would be 2. The same rule applied when there were three or more trials. For example, if a mutant was 1 in one trial and 3 in the other two trials, then the final score would be 3 (Figure M3.6).

No numeric score was assigned in the cold germination screen. Instead, if the two replicates on the same plates (Figure M3.2) had similar phenotypes that were each different from WT, the mutant was scored according to their phenotypes, including 'CS' (cold sensitive), 'CT' (cold tolerant), and 'YG' (yellow green). Mutants tested in only one trial received the score 'SR' (single read).

For the Kanamycin screen, green plants with visible roots were scored as 'R', representing 'resistant', while pale-green plants with very shallow roots were scored as 'S', representing 'sensitive'. If both 'R' and 'S' appeared in one line, the mutant was scored as 'seg'.

Validation of mild phenotypes

To validate the phenotypes we observed, the sizes of some randomly chosen mutants with sensitive or tolerant phenotypes as well as their corresponding controls were measured and compared. As we were using photos for measurement, the relative length/width compared to a fixed reference length was necessary to enable comparisons among different plates. As most of the plates we used (especially in the later stage of this study) have the 6x6 grid patterned bottom, the length of one grid was chosen as the reference length. Size of a single plant was calculated by the product of the relative length and relative width. T-tests were applied to assess statistical significance of the difference in size between the chosen mutant and the control.

RESULTS

Genotyping and genotype groups

A total of 250 SALK lines were genotyped for T-DNA insertions, including 181 DR, 37 nDR and 32 SCR lines (Table 3.1). There are two different SALK lines for two DR genes, one nDR gene and three SCR genes (Table S3.2; green cells in column 'gene'), only one of which were involved in the root and stress screens though all were grown for seed collection. The SALK lines were divided into three genotype groups (Table 3.1). One or more homozygous (HM) knockout plant(s) were identified in 185 (74%) SALK lines, forming the HM group. Both heterozygous (HT) and wild type (WT) plants were present in 27 (11%) SALK lines without homozygous plants, constituting the potentially lethal (PL) group [for which homozygous knockout mutants may be inviable]. The wild type (WT) group contains 34 (14%) SALK lines in which all plants were wild type. Others (OT) include 4 lines (2%) with only HT plants or plants with unknown genotypes.

For WT and OT groups, phenotypes may not be associated with target genes. In WT lines, the T-DNA insertions were not at their expected places, with their real locations unknown. Both DR and control groups included WT lines, which were probably caused by incorrect mapping of T-DNA locations [37]. Two WT lines (SALK_081322 and SALK_040220C) were also recorded as WT in a chloroplast function database (http://rarge-v2.psc.riken.jp/chloroplast/), agreeing with our results. DR knockout mutants have the highest percentage of WT (16%), similar to what was reported in the chloroplast functional database [37], while the percentage is lower in nDR (8%) and SCR (9%).

Lines with only HT plants may indicate abnormal insertion events. For example, perhaps only a short segment of the T-DNA left border was inserted instead of the whole region, and

therefore did not block the (LP+RP) reaction. In this case, the banding patterns of HT and HM would be indistinguishable. The small insertion might exert no influence on transcription thus a full-length mRNA could still be produced. Therefore, the HT lines were not considered knockout mutants.

One (Mutant 21) of the two lines with unknown genotype did not have amplification of the wild type allele in the control (wildtype Col0 DNA). This failure of amplification might indicate a problem with the LP primer. The (LB+RP) primer combination amplified in the pooled sample, indicating that nothing was wrong with LB or RP primers and the sample DNA. The control DNA worked well for (LP+RP) primers of other SALK lines using the same PCR mixture and PCR machine, eliminating the potential problem of the control DNA and other PCR-related factors. Mutant 21 was kanamycin-resistant and not segregating, thus could possibly be HM. As to the other line (Mutant 3_30; SALK_067058C), which was HM in a leaf phenomics study [38], no PCR product was detected.

Potentially lethal (PL) SALK lines

DR genes have a higher percentage of potentially lethal SALK lines (12%) than both SD (9%) and nDR (8%). Abnormal seedlings were detected in 63% of PL lines grown on soil (Figure 3.1c,d), and defective seeds were found in siliques of heterozygous plants in 41% of PL lines (Figure 3.1a,b; Table S3.3), supporting the lethality of the absent HM genotype. About 30% of PL genes were confirmed as essential to plant survival by other research groups, and 15% have published morphological phenotypes (Table S3.3).

Evidence of HM knockout lethality was found in root and other screens as well. Mutant 45 segregated for small, red seedlings in the sucrose screen (Figure 3.2). For mutant 56, small

grey seedlings were found in the ABA screen, and a few tiny white seedlings occurred in the mannitol screen, in agreement with its reported lethal phenotype [39](Figure 3.2).

Of the 20 PL lines tested in root or stress screens, most were scored as 3 (no difference from WT), agreeing with the fact that these plants were HT or WT for T-DNA insertions. The expected 'seg' phenotype rarely appeared, perhaps because the number of seeds for each line was too small to be confident of including HM seed. Though two or three of 10-14 seeds from selfed HT plants were expected to be HM, the frequency of HM plants might be less than 25%. Consistent with this possibility, no line showed 'seg' phenotypes in more than two screens, even for the confirmed lethal mutants (eg. Mutant 56).

In two PL lines, phenotypes were observed in most but not all plants, while only one quarter or fewer of seedlings were expected to be HM. The observed phenotype in one mutant (mutant 3_23; SALK_080169C) is similar to its reported phenotype [40], yet it is unknown why so many seedlings showed phenotypes. These lines perhaps segregated at atypical ratios or the T-DNA insertion caused a dominant phenotype, with their HT plants revealing phenotypes as well.

Interestingly, a few tolerant phenotypes were found, especially in the ABA screen. Most of these phenotypes were mild (score 4) except for one in sucrose (Mutant 149). Rather than being a mutant effect, the slightly larger size might be within the normal range of wild type Arabidopsis plants, or due to unknown environmental factors.

Homozygous (HM) SALK lines: Soil growth phenotypes

As many as 14% (18/130) of DR HM mutants, but no SCR or nDR mutants, showed phenotypes under normal growth conditions while growing plants for fresh seeds or genotyping (Table S3.4)(Table 3.2). Most of the phenotypes were described as 'small' (Table S3.4), and

could be associated with many factors including late germination, retarded growth, dwarfism, seedling lethality, watering or seed quality. Therefore, they were grouped based upon more detailed descriptions in addition to 'small'. For example, a mutant with description 'small and yellow green' would be put in the 'pigment' category. There are seven categories in total for soil growth phenotypes of DR HM mutants (Table 3.2).

Phenotypes in the 'lethal' category may not derive from the target genes. Small, dying plants did not survive to the 6-8 leaf stage when leaves were collected for DNA extraction, therefore HM plants were not identified in PCR. Instead, lethal phenotypes might be caused by T-DNA insertion in non-target genes, or by environmental factors. Interestingly, one of the five genes in the 'lethal' category was reported to be essential: Its knockout mutant has abnormal chloroplasts thus cannot survive without exogenous sucrose [41]. The reported phenotype belongs to a mutant (Feldmann T-DNA line, no. 2755) different from ours (SALK_021962C), which experienced PCR problems, therefore the only putative HM plant might not be truly HM.

The distribution of phenotypes among other categories was not even, with the largest non-lethal category being 'pigment', containing four lines (Table 3.2). The enrichment of pigment mutants was not due to a high percentage (32.3%; 98/303) of chloroplast-targeting proteins, the elimination of which frequently results in a pigment defect [42], as only one out of the four proteins in 'pigment' is located in the chloroplast.

All three DR genes in the 'leaf' category were related to RNA metabolism (rRNA processing, tRNA/rRNA methyltransferase, RNA modification), a functional term occurring at a low frequency (4.2%, as 17 of the 409 genes with HM SALK lines in PhenoLeaf belonged to the GO category 'DNA or RNA metabolism') in leaf phenotypes [38]. Two of the three proteins were chloroplast-targeting, and both were in PhenoLeaf [38]. SALK_005531C (Mutant 40,

AT5G15390) had reduced trichomes in our study, yet was no different from WT in PhenoLeaf, where trichomes may not be scored. For gene AT4G21770, SALK_039518C (Mutant 1_49) was reported to have no phenotype under normal conditions, as we also observed. Small, curled leaves were found in another SALK line (SALK_149232C) for the same gene (Figure 3.3d). The T-DNA insertions were at different locations in the two mutants, with SALK_149232C in an intron and SALK_039518C in the 5'UTR, presumably contributing to their morphological difference.

Though most soil growth phenotypes were manifested in a few rather than all plants in a particular mutant line, 'seg' depicts those with about 25% of seedlings showing phenotypes. Two of the three 'seg' mutants (135 and 177) experienced PCR problems: amplification was poor in mutant 135, whereas in mutant 177 the (LP+RP) reaction failed in one trial. As a result, their HM plant(s) might in fact be HT. In addition, both mutants have published knockout phenotypes. Mutant 135 corresponds to a known essential gene (AT3G20070) [43, 44], so the soil growth phenotype (slightly smaller stature and fewer siliques compared to WT) may not be from HM plants. Instead, its segregation for lethality was reflected by the appearance of a few stunted plants in the root screen. As for mutant 177, a gamma-ray-induced mutant as well as a different SALK line of the same gene revealed blocked lateral root initiation, small bushy shoots, and male sterility [45], partly consistent with the small and abnormal seedlings we observed. In mutant 97, the segregating phenotype for tiny seedlings agreed with the light green seeds in HT siliques. Different from this observation, the published phenotypes include slightly early flowering and reduced responsiveness to GA and BR treatment during seed germination [46]. Therefore, the 'seg' phenotype of mutant 97 is likely to be unrelated to the target gene.

The ‘multiple’ group describes cases in which distinct phenotypes were observed in different individuals of the same mutant line. In mutant 115, one plant was late flowering, one had reduced fertility, and one was small, all being involved in the reported phenotypes [47]. In addition, the ‘flowering’ mutant (mutant 11) was early flowering, while the ‘seed’ mutant (mutant 131) had abnormal seed.

In summary, there are 12 DR HM mutants with soil growth phenotypes, after removing those likely not caused by the mutated target genes (all ‘lethal’ except mutant 99; all ‘seg’ except mutant 177). The soil growth PP in DR HM mutants thus became 9.2% (12/130).

Homozygous (HM) SALK lines: Root and stress screen phenotypes

Not all HM SALK lines were included in the root and stress phenotype dataset for various reasons. In early trials, plates were not photographed if nothing striking was noticed. In addition, a few plates were contaminated. All of these reasons led to ‘single read’ (Methods) results, which were not considered a valid phenotype score. One HM SALK line (SALK_017317C) was not tested because it was not yet in hand at the time of the screen. For gene AT4G21770 with two SALK lines, SALK_039518C was tested instead of SALK_149232C.

Segregating phenotypes

Segregating root or stress phenotypes were found in both DR and nDR. There were three ‘seg’ nDR knockout mutants (Figure 3.4), all with reliable genotyping results. Therefore the ‘seg’ appearance might be caused by factors other than scoring HT genotypes as HM, for example, phenotype penetrance being less than 100%.

In DR, six ‘seg’s were found in five mutants, with mutant 135 segregating in both root and sucrose screens (Figure 3.5). Three of the five mutants (Mutants 26, 177, 97) had soil growth

phenotypes, indicating that most 'seg's reiterated morphological changes expressed under normal conditions rather than reflecting root or stress specific phenotypes. As discussed above, genotyping error might account for the segregating phenotypes in mutants 177 and 135, while a background T-DNA insertion may be responsible for the 'seg' in mutant 97.

The non-segregating root phenotypes

A total of six (5%) DR, one (4%) nDR and one (5%) SCR HM mutant(s) showed root phenotypes (Table S3.5). One of these mutants had long roots, while the others had short roots, consistent with the observation that long roots appear much less frequently than short roots among published knockout phenotypes [17]. Four of the six DR root mutants had a striking phenotype (scored 1 or 5), whereas all nDR and SCR root phenotypes were mild (scored 2).

Most published root phenotypes co-occurred with other morphological changes, particularly dwarfism [17]. In contrast, only one root mutant (Mutant 51) had a soil growth phenotype, indicating that these genes tended to be involved in root-specific processes. Five out of eight root mutants correspond to proteins located in chloroplast or mitochondrion, suggesting over-representation of pathways regulating root development through signaling crosstalk between chloroplast/mitochondrion and nuclear genomes.

Hormone signaling played an important role in root development [48, 49]. ABA regulates root growth through interaction with other hormone signaling or synthesis pathways [50], promoting root growth at low concentration (<1μM) and inhibiting root growth at high concentration [51]. Therefore, mutants with defects in ABA signaling might have disturbed root development, and vice versa. The SCR root mutant was indeed sensitive to ABA, yet none of the DR mutants had ABA phenotypes, indicating that DR genes' functions differed from the control group in root growth regulation.

Among the six DR genes with root phenotypes, three might indirectly affect protein synthesis efficiency according to their annotation, including ribosomal protein S4, pseudouridine synthase and anthranilate phosphoribosyltransferase. Pseudouridine synthase is involved in RNA modification [52] and Anthranilate phosphoribosyl-transferase participates in tryptophan biosynthesis. Though no stress condition was applied in the root screen, two genes were implicated in stress response: NDF6 is likely to be a subunit of NDH, which helps to alleviate oxidative stress in chloroplasts [53]; ATTPR2, a putative co-chaperone of Hsp70/Hsp90, interacts with Hsp90, the expression of which is induced by a variety of stresses [54]. The remaining protein, a CAAX amino terminal protease family protein, might be involved in signal transduction, as CAAX proteins have essential roles in mammalian signaling pathways [55].

The non-segregating root phenotypes

DR genes with striking stress phenotype

About 7% of DR HM SALK lines, representing 9 DR genes, showed striking phenotypes (with a final score of 0, 1, or 5) in stress screen(s) (Table S3.6). The screens with the most striking-phenotype mutants are sucrose and cold germination, each containing three. These two screens were the only ones in which striking phenotypes were found in the nDR group.

Among the 9 DR mutants with striking stress phenotypes, two had phenotypes in more than one stress screen. Mutant 34 was sensitive to water stress, including ABA, salt and sucrose screens. Though it scored ‘single read’ in the mannitol screen, strong sensitivity to mannitol was also suggested (Figure S3.1). In contrast, it was indistinguishable from WT under temperature stress. Mutant 167 was particularly responsive to cold stress, showing tolerant phenotypes in both cold growth and cold germination screens. Whether it is involved in heat stress remains to be tested, as only single reads were obtained in both heat and heat recovery screen.

Two genes had published phenotypes for their knockdown or knockout mutants, namely, AT4G13670 (mutant 39) and AT2G31040 (mutant 65). The RNAi line of AT4G13670 was sensitive to heat stress (30 degree, 5 d) [56], yet its SALK line (SALK_096411C) had no phenotype in our heat screen, perhaps because we used a different condition (34 degree, 14 d). Instead, a phenotype (yellow green) similar to one published under heat stress [56] was detected in our cold germination screen (Figure S3.2), implying that the protein might be required for normal chloroplast development under both hot and cold conditions. The smaller size of mutant 65 reported by others (SALK_05729) [57] is not observed in our study, perhaps because the reported size difference is not striking. Similarly to mutant 39, mutant 65 was yellow green under cold stress, possibly due to chloroplast protein synthesis reduction [57], which might be aggravated under cold stress.

The two largest functional categories of DR genes with striking stress phenotypes were transcription/translation and signaling/stress response. Four out of nine genes were implicated in transcription or protein synthesis (113, 3_36, 39, 65), including a SET domain protein, a pseudouridine synthase family protein, PTAC5 (plastid transcriptionally active 5), and AtCGL160 (Arabidopsis CONSERVED ONLY IN THE GREEN LINEAGE160) [57]. SET domain proteins are involved in epigenetic control of transcription [58]. PTAC5 is a necessary component for plastid-encoded RNA polymerase (PEP)-dependent transcription under heat stress [56]. Though ATCGL160 is not directly involved in translation, its knockout mutant has less chloroplast protein than WT, presumably due to the reduced translation rate caused by insufficient ATP [57].

Three of the 9 DR genes with striking stress phenotypes were associated with signaling or stress response, according to their predicted functions. Mutants 34, 39 and 3_35 correspond to a

phosphoinositide binding protein [59], PTAC5, and a tetratricopeptide repeat (TPR) protein, respectively. Phosphoinositide binding proteins are the effectors of PtdIns(3)P [60], which plays important roles in diverse physiological processes, including ROS production in response to salt stress [61]. As mentioned above, PTAC5 is important for chloroplast transcription under heat stress. TPR-containing proteins may participate in hormone signaling [62] or function as co-chaperones of heat shock proteins [54].

Translation or stress response were also well represented in SCR genes with striking stress phenotypes, with one involved in defense response and the other in tRNA modification (Table S3.6). In contrast, none of the nDR genes with striking stress phenotypes belong to the two categories (Table S3.6): one is implicated in lipid metabolism and the other is unknown.

DR genes with mild stress phenotypes

There were 33 mutants of DR genes with mild phenotypes (scored 2 or 4) in stress screens. As discussed in the 'soil growth phenotypes' section, mutant 1_49 might not be a knockout and thus was removed from the list of DRs with mild stress phenotype.

Among the remaining 32 mutants, five also revealed striking phenotypes (including soil growth phenotypes) in other screens. Mutant 3_35 and 3_36 were sensitive in both cold growth and sucrose screens, while mutant 167 was tolerant in these two screens, indicating a positive correlation between cold growth and sucrose. In addition, two mutants had soil growth phenotypes: Mutant 26 had small silver leaves; Mutant 160 was small and yellow green. The basis for correlation between the soil growth phenotypes and stress-triggered phenotypes, sucrose sensitivity for mutant 26 and cold tolerance for mutant 160, was unclear.

Two of the 27 mutants with only mild phenotypes detected (Mutant 63 and 83) had phenotypes in multiple screens. Mutant 63 was sensitive to ABA, mannitol and sucrose, and was

tolerant of cold growth. The corresponding gene is involved in protein modification, therefore may affect a variety of proteins, perhaps accounting for the wide range of phenotypes. Mutant 83 was ABA tolerant and salt sensitive, consistent with its annotation as a desiccation-induced protein.

Five of the 27 mutants with only mild phenotypes have published loss-of-function phenotypes. Two were reported to have cellular biological (CLB) phenotypes [17] which were undetectable under our test conditions. One mannitol sensitive mutant (Mutant 67) had a conditional phenotype triggered by hrpA and DC3000 strains [63], suggesting that the protein might participate in crosstalk between biotic and abiotic stress signaling pathways. The other two genes (AT5G11450; AT4G31770) were reported to cause visible morphological changes [64] and lethality [65] upon deletion, respectively. The mutants we used for both genes (Mutant 78, SALK_122077C; Mutant 58, SALK_024527C) were different from those with published phenotypes (Mutant 78, an unknown T-DNA insertion line; Mutant 58, SALK_061118), perhaps explaining why we did not observe the same phenotypes. Instead, their stress phenotypes may reflect the knockdown effect.

None of the 27 genes with only mild phenotypes had functional annotations implicated in signal transduction or stress response, whereas one of the six SCR genes (AT5G62390) with a mild stress mutant phenotype was implicated in heat/cold/unfolded protein response. Instead, the largest category (8/27 genes, 30%) in the mild-phenotype DR group was ‘unknown’ (Table S3.7; empty cells in column ‘protein description’). The high proportion of unknown proteins among mutants with mild phenotypes was not unique to DR. Three of the four unknown SCR proteins were in the mild-phenotype group (Table S3.7, Table S3.5). Four of six nDR genes with mild

phenotypes were unknown (Table S3.7), while unknown proteins compromised only 11% (5/23) of the nDR genes with striking or no phenotypes (Table S3.5).

PP comparison between DR and the control groups among stress screens

As can be seen above, some genes have published severe knockout phenotypes which were absent in our mutants for the same genes. If no PCR problem occurred and the published phenotype was confirmed, the mutants used in our study were then considered to be knockdown (Table S3.9). Consequently, these presumably knockdown phenotypes were not used in calculating the PP (phenotype percentage) below.

The percentage of DR HM mutants showing phenotypes (29%) in at least one stress screen, hereafter referred to as the overall stress PP, was lower than SCR (40%), suggesting that DR HM mutants were not highly involved in water and temperature stress response. On the other hand, the overall stress PP of DR HM group (29%) is similar to nDR HM group (28%), consistent with their similar copy number (Methods). Relatively high SCR PP together with similar DR and nDR PPs were observed for striking phenotypes (Table 3.3), implying that this pattern is reliable and is not affected by possible misscoring of mild phenotypes (score 2 or 4).

Mutants with phenotypes in two or more stress screens may represent genes involved in crosstalk among different stress signaling pathways. The percentage of such mutants was lower in the DR group (5%) than both control groups (SCR, 10%; nDR, 7%) (Table S3.5). Therefore, DR genes were not highly involved in crosstalk between multiple stress response pathways, compared to other fully conserved singletons.

The percentage of DR HM mutants being sensitive or tolerant was lower than SCR HM mutants in seven stress screens (Table 3.3; Figure 3.6). Due to the small sample size (<30) of SCR HM SALKs, the differences in PP between DR and SCR groups were not statistically

significant (Table S3.8). Yet, some differences were obvious thus worth further testing using a larger SCR sample. The most striking difference was in cold germination, where the PP of the SCR group is almost four times as high as that of the DR group (Table 3.3). In contrast, DR mutants were more prone to reveal phenotypes in the salt screen than SCR mutants, none of which had salt phenotypes. High salt (NaCl) stress induces both osmotic stress and ion toxicity. As no mannitol phenotype was found in any of the salt mutants, the corresponding genes might be involved in detoxification or ion homeostasis rather than osmosis. Five of seven DR salt mutants had no ABA phenotype (Table S3.5), suggesting that these genes tended to participate in ABA-independent signaling pathways.

The PP of DR mutants was similar to that of nDR mutants in most screens, except for salt and ABA (Table 3.3; Figure 3.6). Similarly to SCR, there was no salt mutant in the nDR group. The difference of PP between DR and nDR groups in salt and other screens was not statistically significant, due to the small number of nDR genes with HM SALKs (<30). However, if the SCR and nDR were combined as a single control group, the difference between DR and the control for salt PP is slightly significant (p value=0.0434, Table S3.8). In the ABA screen, the nDR PP was higher than the DR PP, implying that DR genes were less involved in ABA-mediated processes during seed germination and early seedling development: stress response, germination [66], plant growth or water regulation [67].

There are more sensitive phenotypes (scored 0, 1, or 2) than tolerant phenotypes (scored 4 and 5) in all three groups, consistent with a prior study [26]. Sensitive PP exceeds tolerant PP in most screens except for ABA in DR and nDR groups (Tables 3.4, 3.5). The nDR group has more ABA tolerant phenotypes than sensitive ones, whereas in the DR group the numbers of tolerant and sensitive ABA phenotypes were equal.

Tolerant DR mutants were found in most screens except heat recovery and salt, whereas in the control groups (nDR and SCR) tolerant phenotypes were only detected in ABA and cold germination screens. Moreover, DR tolerant PPs in ABA, cold growth and sucrose were a bit higher than in other screens (Table 3.5). For sensitive phenotypes, DR had lower PP than both control groups in cold growth and cold germination screens (Table 3.4), perhaps reflecting a lack of positive regulators in response to low, non-freezing temperatures.

DR genes without observed phenotypes

There are 70 DR HM mutants with no observed phenotypes, after excluding the knockdown mutants (Table S3.9). Of these 70 DR genes, eight had published loss-of-function phenotypes that were visible under normal conditions and two were essential (Table S3.10). Several reasons might explain why we failed to observe the same phenotypes, the major one being that seven of the ten mutants we screened were different than those with reported phenotypes. Though different mutants should reveal the same phenotype(s) if the genes were truly knocked out, T-DNA insertions are not always able to eliminate the target gene product [68, 69]. As a result, 'leaky' products might attenuate or totally mask knockout phenotypes. In addition, non-striking soil growth phenotypes (eg. Mutant 120, SALK_007870) were not thoroughly/intentionally screened for in our study (Method). Further, four of the eight published phenotypes were about siliques or flowering (Table S3.10), reproductive stage phenotypes that were not covered in our root and stress screens. Finally, PCR problems may be responsible for the absence of a phenotype in one mutant (Mutant 111, SALK_093546C). Consequently, the two HM plants were not albino as reported [70]. The ten genes were removed from DR genes without observed phenotypes.

The largest functional category in the remaining 60 DR genes without observed phenotypes was ‘unknown proteins’, constituting 28% (17/60) of this DR genes’ subset (Table S3.11). The percentage was higher than DR genes with phenotypes (20%; 13/66) and the genome-wide average (18%, the percentage of protein-coding genes without known protein domains), but not as high as the mild phenotype DR group (30%; 8/27). Therefore, DR genes with unknown function were less likely to show phenotypes than other DR genes, and they tended to have mild, almost undetectable phenotypes. The high percentage of unknown proteins was also observed in nDR genes without observed phenotypes (24%, 5/21), but not in the SCR group (8.3%; 1/12) (Table S3.11).

Chloroplast targeting DR genes and their phenotypes

Of the sampled DR genes, 37% (66/179) encode chloroplast-located proteins. Removing those with SALK lines in WT or OT group (Table 3.1) or likely being knockdown, there are 55 chloroplast-targeting DR genes, 42% (23/55) of which had presumable knockout phenotypes (Table S3.12). The phenotype percentage of chloroplast-targeting DR genes was lower than other DR genes (47%; 43/92), suggesting that DR proteins located in chloroplast were not more likely to have knockout phenotypes than other DR proteins.

All four main types of observed phenotypes (PL, soil growth, root and stress) were found in DR chloroplast proteins, which occurred at a relative low frequency in soil growth (non-lethal) phenotypes and a relatively high frequency in root phenotypes (Table 3.6). Moreover, the proportion of DR proteins varied among stress screens as well and was high in genes with sucrose and cold germination phenotypes (Table S3.13).

DISCUSSION

All being paleo-polyploid, angiosperms serve as an outstanding model for studying fates of genes after duplication [71]. Among a variety of possible fates [72], the long-term fixation of duplicated copies is considered to be rare, non-random and important [3]. As a result, it has been heavily researched and relatively well explained by a number of hypotheses [9, 73, 74]. In contrast, neither the importance nor the cause of persistent single copy status is well understood, though such 'duplication-resistant' genes do not occur by chance [6, 34]. Intricate and diverse as the underlying mechanisms of duplication resistance may be, it remains a reasonable assumption that the biological roles of DR genes in plants hold an important piece of the answer. Indeed, several possible explanations for single-copy preference derive from features of annotated gene functions [4, 8].

Here we investigated DR genes' functions from the perspective of empirical phenotypes revealed by knockout mutants. There are four major phenotype categories in tested DR genes and control genes, namely, PL (potentially lethal), soil growth, root and stress, with the latter three being associated with homozygous (HM) T-DNA insertion (SALK) lines only. Compared to other single copy genes, DR genes were more prone to cause lethal or visible above-ground phenotypes upon T-DNA insertion, as was revealed by DR genes' higher PL and soil growth PPs. This finding was contrary to observations from published datasets, where other conserved singletons have higher PP than DR in each and every phenotype category (Chapter 2). Several factors could have caused this incongruence. For example, phenotypes from genes not involved in any previous dataset may elevate DR genes' PP. Meanwhile, the sampling of control genes happened not to cover genes with published phenotypes. No matter how high the PP might be in a gene group, mutants with phenotypes were still a minority. As a result, the chance of sampling

the corresponding genes through random selection was low. In addition, some phenotypes might have nothing to do with the target genes, resulting in false expansion of PP. Further validation of these observed phenotypes is important. Nevertheless, our result raises the possibility that DR genes might serve more important functions than other fully conserved singletons.

Despite the lack of above-ground phenotypes, the root PPs in control groups were similar to those of DR genes. Six DR mutants had short or long roots compared to wildtype Col0, constituting about 5% of the DR HM set. The corresponding DR genes may tend to function in root specific programs, reflected by the lack of other phenotypes: one mutant had a soil growth phenotype and one a stress phenotype. In particular, DR genes frequently appeared in root growth pathways regulated by chloroplast signals, as three of the six proteins (50%) were located in the chloroplast. In contrast, DR genes rarely participated in the portion of the root growth pathway intertwined with ABA signaling, compared to SCR genes.

DR genes were not highly involved in response to the tested stresses, with lower overall stress PP than SCR genes. This result was expected as no published evidence suggested overrepresentation of stress-related functions for DR genes. Indeed, growing evidence implicates single-gene duplications as key contributors to stress adaptation, consistent with the ongoing availability of this gene class (versus the episodic nature of whole genome duplications) and the need for continuous adaptation to environmental fluctuation. Rather than reacting to environmental stimulus, housekeeping functions seem to be a better fit for DR genes, as was suggested by frequent occurrence of TELO-box and scarcity of TATA-box containing promoters in the unique genes conserved between Arabidopsis and Oryza [7]. Under this hypothesis, severe phenotypes would be a more likely consequence of DR gene T-DNA insertion, supportive of the

higher occurrence of soil growth and potentially lethal phenotypes in DR mutants than the controls.

The relatively low PP of DR genes was seen in almost every stress screen, with the most striking difference relative to SCR in cold germination. Two SCR mutants and three DR mutants showed cold germination phenotypes. One of the SCR genes was pathogenesis-related. Proteins functioning in both cold and disease responses are not rare [75-77]. Moreover, disease resistance genes have generally high copy numbers and great copy number variation among species [78], presumably accounting for their low occurrence in DR genes. The lack of defense proteins, in turn, may contribute to the low cold germination PP in DR genes.

Salt is the only stress for which the PP is higher in the DR group than the SCR group. Based on their lack of osmotic stress phenotypes, DR genes with salt phenotypes tend to be involved in detoxification or ion homeostasis. Similar to DR genes with root phenotypes, they are also more prone to function in ABA-independent pathways. As no salt phenotype was found in the other control group (nDR) as well, the enrichment of salt pathway genes may have been associated with duplication resistance. Yet, as with any other stress, salt stress response is complicated, including the re-adjustment of numerous biological processes [28], making it difficult to clarify its correlation with duplication resistance. An attractive hypothesis is that these genes form a sub-network of salt signaling, within which duplication of any member may disturb overall network function. However, no co-expression or protein interaction was detected among these genes, indicating that they were probably not closely related.

The difference in stress PP between DR and SCR genes was not evident in comparing DR with nDR genes. The similar PPs of DR and nDR genes were expected based on their same copy numbers in the five plant species (Method). Despite the similarity in their proportions of

stress mutants, the nDR group has a lower salt PP and higher ABA PP than the DR group. In addition to drought mutants, the application of exogenous ABA could sort out candidates for various other stresses as well. Therefore, the low ABA PP of DR genes further supports the earlier conclusion that DR genes tend not to react to stress, especially to ABA-mediated parts.

Moreover, DR genes have a low proportion of positive regulators in cold signaling, as revealed by their much lower sensitive PP in the two cold screens than both control groups. Low temperature might favor survival of polyploid plants, as polyploidization sometimes increased plant cold tolerance [79]. During subsequent diploidization, it might confer a selective advantage for cold positive regulators to remain duplicated for a while, for example, favoring survival of future cold episodes. Therefore, they were less likely to occur in a gene group where the extra copies were quickly removed.

Of DR stress phenotypes, 25% (9) were striking and 75% (27) were mild. Predicted functions in stress signaling were only found in DR genes with striking phenotypes, not in those with mild phenotypes. Indeed, about a third of DR genes with mild stress phenotypes were of unknown function. Instead of being involved in the main stress pathways, mild-phenotype genes might have peripheral roles during stress response. On the other hand, the high proportion of unknown functions in the mild phenotype group indicates that unknown genes are prone to revealing non-striking knockout phenotypes. Phenotyping methods that are sufficiently sensitive to detect mild phenotypes may be important in studying genes of unknown function.

In addition to stress signaling, functions implicated in transcription or translation were also enriched in striking-stress-phenotype group. The stress phenotype might derive from reduction of key stress regulatory factors. Alternatively, a broad reduction in protein synthesis may also make plants more vulnerable to stresses. Other than stress phenotypes, disturbance of

genes which affect a group of other genes' production is prone to reveal phenotypes under normal conditions, as can be seen by their high occurrence in root and soil growth phenotype groups. Most of these genes belong to DNA or RNA metabolism, a GO category enriched in DR genes. Therefore, the enrichment of transcription/translation-related genes in multiple phenotype groups indicates that DNA/RNA metabolic DR genes have important functions.

Besides DNA/RNA metabolism, chloroplast is also an overrepresented GO term in DR genes. Chloroplast-targeting DR genes had a lower overall PP (42%; 23/55) to other DR genes (47%; 43/92) in our sample. If chloroplast-located DR proteins were indeed involved in dosage balance with their chloroplast-genome-encoded interactors, the disturbance of such balance via gene knockout is not reflected at the phenotype level. Duplication, on the other hand, might have a larger perturbing effect. Hence, it would be interesting to test mutants where chloroplast-targeting DR genes were duplicated. In addition, the result might imply that the effect of dosage balance disturbance is subtle and thus would not be visible during a few generations.

The proportion of chloroplast-targeting DR genes is distributed unevenly among the four major phenotype groups, being highest in root and lowest in above-ground phenotypes, indicating that they tend to regulate a particular part of, rather than broadly affect, plant growth/development. Similarly, these genes were strongly associated with particular stresses, such as sucrose and cold germination. The enrichment of chloroplast-targeting genes in sucrose mutants was observed in the control groups as well. Being the location where sucrose is produced, the chloroplast is expected to play important roles in sucrose signaling. The correlation between chloroplast-located proteins and cold germination was unique in DR: all DR cold germination mutant genes were chloroplast-targeting, while none were related to chloroplasts in either control group. In contrast, chloroplast DR genes were not highly

represented in cold growth mutants, indicating that these genes particularly respond to cold stress occurring before or during germination.

Agreement with published data in our observed phenotypes was found in some but not all genes with published loss-of-function phenotypes. PCR problems, phenotype mis-scoring, and background T-DNA insertion were among possible reasons, yet the major cause might be the use of different mutants. The phenotype of one mutant was frequently absent in another mutant of the same gene in published datasets (Chapter 2)(Table S3.14), implying that some transposon or T-DNA insertional mutants, SALK lines included, are not real knockouts. Updates on DR knockout phenotypes will occur with further validation. For example, the stress phenotype was merely a knockdown effect, whereas the real knockout mutant has a more severe phenotype. Nevertheless, a majority of our observations remained true for SALK lines used in this study.

The observed phenotypes, whether from knockout or knockdown mutant, serve as a starting point for further investigation of DR genes' functions, and also added new information to the known knockout/knockdown phenotypes. As the first thorough screen of stress-related phenotypes for DR mutants, these results depict a rough yet relatively complete picture of their phenotypic features, some of which appear to be related to duplication resistance. These features may inspire new ideas for future research, meanwhile taking us one step closer to demonstrating DR gene functions as well as clarifying the underlying force(s) favoring duplication resistance.

CHAPTER 4

DUPLICATION AND OVEREXPRESSION OF DUPLICATION-RESISTANT GENES: A GLIMPSE INTO POTENTIAL OUTCOMES

Chengbo Zhou, Kenneth Feldmann, Kathryn Millward and Andrew H. Paterson. To be submitted to Physiologia Plantarum.

ABSTRACT

In contrast to the highly duplicated nature of plant genomes, 'duplication-resistant' (DR) genes have been recurrently restored to low dosage following independent genome duplications in various species. Their low copy status, representing a highly biased fate after gene duplication, implies that one copy of these genes is necessary for maintaining proper fitness but that multiple copies are less beneficial than single copies, or even deleterious. Complementing a screen for knockout (KO) phenotypes that focused on the necessity of DR genes, a phenotype search was conducted on genotypes with DR genes artificially duplicated or overexpressed, to examine the consequences of having multiple copies of these genes. Specifically, Arabidopsis addition (AD) lines each containing an extra copy of a target gene to mimic gene duplication, and overexpression (OE) lines with DR genes downstream of 35S promoters to amplify gene expression, were phenotyped in a similar manner as KO mutants. The observed AD phenotypes show DR genes to be more prone than other single copy genes when duplicated to cause phenotypes, all under stress conditions and most being mild. Yet, AD and OE phenotypes of DR genes are not always negative, as stress tolerant phenotypes occurred at an almost equal frequency as sensitive ones. Seedling phenotypes, absent in AD lines, were found in OE lines at a higher percentage than KO mutants. Genes with both OE and KO phenotypes, constituting approximately a third of the OE sample, are considered dosage sensitive. Thus, dosage sensitivity may be one major cause of duplication resistance, yet is not prevalent in organelle-targeting genes and those with a lethal KO phenotype. These observations increase knowledge of duplication resistance and its intricate nature. The plant resources created in this study warrant further investigation and will certainly benefit continuing effort to understand both duplication resistance and plant gene function generally.

INTRODUCTION

The fates of duplicated genes are an important part of gene and genome evolution [1]. To retain or purge a copy of each newly duplicated gene pair can have an enormous collective impact on genome biology and evolution, especially following whole genome duplication in which tens of thousands of genes are duplicated simultaneously. While several gene functional groups are preferentially preserved in duplicate [2-7] and comprise large multigene families, Most gene functional groups show post-duplication gene preservation/loss rates that are indistinguishable from the genome-wide average. Such 'neutral' loss of duplicated genes presumably involves inactivating mutations opposed by very weak selection [8], although active mechanisms of gene elimination have also been suggested [9].

A small group of 'duplication-resistant' (DR) genes [10] have been recurrently restored to low dosage following independent duplication events in taxa as divergent as plants, fishes, and yeast. The existence of DR genes is most renowned in angiosperm genomes, all of which experienced one or more whole genome duplications (WGDs) [11] and numerous small scale duplications (SSDs) [12]. Thanks to the richness of ancient duplication events, various groups of plant DR genes have been identified based mainly on their copy numbers among several plant species, and their features described [13-15]. While some common features of these different gene sets have been discerned (Chapter 3), a clear explanation of duplication resistance is not yet evident.

The defining characteristic of restoring low gene dosage, observed in divergent plant genomes with varying evolutionary rates, suggests that duplicated copies of DR genes disappear relatively rapidly. Sequence divergence due to fast evolution [16] and sequence erosion by accumulated mutations [17] are among causes of duplicate gene removal. Given that DR genes

are widely conserved, they are presumably slow-evolving [15], making the more likely scenario that duplicated copies were silenced and the non-functional sequences degenerated within a relatively short period. Therefore, it is reasonable to assume that their duplication may lead to some negative effect that was selected against.

It is not rare that gene duplication reduces fitness of an organism. Several severe human diseases are a direct consequence of gene duplication, for example, Charcot-Marie-Tooth (CMT), Parkinsons and Alzheimers diseases [18]. Such gene duplication-associated mutations, on the other hand, have been rarely reported in plants, perhaps because plant genomes are relatively tolerant to duplications, which occur frequently at various scales by natural causes. In Arabidopsis, where transgenic techniques are well developed, one can artificially 'duplicate' a chosen gene by transforming a copy into the genome. The resulting transgenic 'addition (AD) lines' (detailed in 'Materials and Methods'), allow visualization of direct outcomes from DR gene duplication, and thus may aid in the interpretation of duplication resistance.

For disorders resulting from gene duplication, the dosage increase is usually the cause [19-21]. The normal function of a protein complex, regulatory network or pathway may depend on a proper relative dosage of each member to others, and the duplication of one member would disturb the dosage balance [22]. Further, elevated protein amounts alone may cause problems. A high concentration of certain proteins may trigger the formation of aggregates [18, 23] or encourage non-specific binding to other proteins, preventing themselves or others from fulfilling their duties. Therefore, increasing gene expression level is considered an alternative strategy to evaluate duplication effects.

Overexpression (OE) lines, in which target genes are constitutively overexpressed by the CaMV 35S promoter (detailed in 'Materials and Methods'), were made to examine the

consequences of dosage increase for DR genes. The expression elevation in OE lines is expected to be more striking than that of gene duplication, thus may magnify mild AD phenotypes and render them visible. For genes that are not constitutively and ubiquitously expressed, ectopic expression may also occur, yet is likely not to mask the overexpression effect in most OE lines, as was implied by the similar phenotypes induced by 35S promoter and 35S enhancer [24-30] (which theoretically does not alter the endogenous expression pattern [31]).

As a powerful tool in gene functional study, OE lines will contribute to the interpretation of duplication resistance. Being an important variable in affecting evolutionary fate after gene duplication, gene function holds an irreplaceable piece toward solving the puzzle of persistent single copy gene dosage. Overexpression (OE) phenotypes, in many cases opposite the knockout (KO) phenotype of the same gene [25, 27, 32, 33], reflect gene function as KO phenotypes do. For example, an early flowering KO phenotype may correspond to a late flowering OE phenotype, reconfirming the protein's presumed role in flowering time control. Besides being a nice complement to KO phenotypes, OE lines would also shed light on functions of genes without KO phenotypes or lacking homozygous KO mutants [30].

In order to test the effect of duplication or expression increase for DR genes, and also to continue their functional investigation following our previous KO mutant study (Chapter 3), we made AD and OE lines for 11 and 64 DR candidates whose SALK lines were involved in the KO phenotype study, respectively. These lines, together with the AD and OE lines of some control genes, were screened for their root and stress-response phenotypes as were KO mutants (Chapter 3). 'Soil growth phenotypes', were also noted while growing AD or OE seedlings on soil under normal conditions. The phenotypic features of DR genes, compared to non-DR genes and KO mutants, were described.

MATERIALS AND METHODS

Target genes for AD and OE mutants

The initial Arabidopsis DR gene list contains strict singletons (SSs), which are single copy in five plant species (*Arabidopsis thaliana, Carica papaya, Populus trichocarpa, Vitis vinifera, and Oryza sativa*), and protein domain (PD) genes, which are single copy in *Arabidopsis thaliana* and *Oryza sativa* and have protein functional (Pfam) domains that are significantly enriched in singletons [34].

The initial DR candidates conserved in at least 15 of the 16 genomes (*Manihot esculenta, Ricinus communis, Populus trichocarpa, Medicago truncatula, Glycine max, Cucumis sativus, Prunus persica, Arabidopsis thaliana|Arabidopsis lyrata, Carica papaya, Citrus sinensis|Citrus clementina, Eucalyptus grandis, Vitis vinifera, Mimulus guttatus, Aquilegia coerulea, Sorghum bicolor|Setaria italica|Oryza sativa|Brachypodium distachyon, Zea mays,* where average counts were taken for two arabidopsis, four diploid grass, and two citrus, with the exception that the count cannot be zero as long as one lineage is nonzero) were considered the final DR candidates (Table S3.1). From 179 final DR candidates with their SALK lines ordered (Table S3.2), 11 and 64 genes were randomly selected for making addition (AD) and overexpression (OE) lines, respectively (Table M4.1; Table M4.2).

The initial DR candidates conserved in less than 15 of the 16 genomes were included in the control group and named ‘nDR’. The control group also contains single copy random (SCR) genes, which are Arabidopsis singletons but not all single copy in the other four species (*Carica papaya, Populus trichocarpa, Vitis vinifera, and Oryza sativa*). From the 36 nDR and 29 SCR genes with their SALK lines ordered, AD lines were created for 14 genes and OE lines were

made for four genes (Table M4.1; Table M4.2). As the number of control genes in AD and OE mutants was small, SCR and nDR genes were considered a single control group instead of two.

Creating AD and OE lines

Both OE and AD lines were transgenic. OE transgenic constructs expressed full length cDNA under the cauliflower mosaic virus 35S promoter. AD transgenic constructs contained the genomic region of a target gene including the 1kb upstream and 500bp downstream flanking sequences, to attempt to capture their endogenous promoters and possible regulatory sequence downstream, respectively. The maximum length of flanking sequences were included in AD constructs for genes located less than 1kb away from their upstream neighboring genes and/or less than 500nt from their downstream neighboring genes. If a target gene has a distance less than 1kb from its upstream gene or less than 500bp from its downstream genes, the non-coding region flanking the gene was included as much as possible.

Genomic DNA was extracted using the Promega Wizard genomic DNA purification kit; colonies containing the BAC and cDNA were ordered from ABRC. BAC DNA was extracted following David Mark's protocol in Molecular Cloning 3rd edition [35], while cDNA was extracted by the Qiagen QIAprep Spin Miniprep Kit.

Upon proper dilution (typically 1:1000), DNA was amplified by PCR, using Takara's PrimeSTAR HS DNA polymerase to avoid errors during amplification. The PCR product was cleaned (Qiagen Qiaquick PCR Purification kit), and the size checked on an agarose gel. Adenine (A) overhangs were added to the cleaned PCR product with correct size. PCR products with A overhangs were integrated into a Gateway entry vector (Invitrogen pCR8/GW/TOPO TA Cloning kit), which was then transformed into one shot competent E. coli cells.

After patching on selective LB plates, plasmid DNA was extracted from each patch and digested with proper restriction enzymes. DNA from the patch(s) with desired insertion was extracted (Qiagen QIAprep Spin Miniprep Kit) and sequenced. For entry clones without a mismatch, a LR clonase reaction was performed with the destination vector (pEarleyGate 100 for OE constructs, and pEarleyGate 301 for AD constructs). The product was transformed into E.coli. DNA was extracted from desired clones using the procedure described in the above paragraph.

The border sequence of the destination vector was sequenced. The destination vector with the correct border sequence was transferred into GV3103 Agrobacterium through electroporation. Colonies with successful transformation was identified by Colony PCR. The confirmed colony is ready for Arabidopsis transformation.

Arabidopsis transformation method is modified from US patent 6353155 (http://patents.com/us-6353155.html). For each transgenic construct, 50ml LB with OD600 >2.0 was diluted with 100ml of 6% sucrose solution to reach an OD600 between 0.8 and 1. Silwet-L77 (0.03%) was added to the diluted LB solution as a surfactant. About ¾ of the solution was poured into a large weigh boat, in which we dipped the inflorescence of each chosen Arabidopsis plant for ten seconds. Dipped plants were laid horizontally in a flat covered by a clear plastic dome, kept in dark at room temperature overnight, then moved to a growth chamber.

Seeds harvested from the dipped plants were germinated on plates containing 50 ug/ml kanamycin antibiotics. Resistant seedlings were transferred to soil and their seeds collected at maturation.

Phenotyping

ABA, mannitol, salt, sucrose, heat, heat recovery, cold growth and root screens were done on AD and OE lines. Seeds were sterilized by 50% clorox solution with Triton X-100 (two

drops per 100ml solution) for 8 minutes, and then rinsed three times with sterile water. Sterilized seeds were planted on 0.5xMS (Murashige and Skoog) medium with 5g/L sucrose in heat, heat recovery, cold growth and root screens. MS medium (5g/L sucrose, 5g/L 2-(N-morpholino)ethanesulfonic acid (MES)) supplemented with 1.5μM ABA and 375mM mannitol was applied in ABA and mannitol screens, respectively. For salt screen, MS medium (5g/L sucrose) was supplemented with 125mM NaCl, and for sucrose screen, MS medium contained 300mM sucrose.

Six lines or five lines with control (wildtype Col0) were planted per square plate (15 x 100 x 100mm), and each line occupied one column of the bottom 6x6 grid. In each line about 10-15 seeds were planted evenly on the surface of the medium, in a straight line parallel to one side of a plate.

After planting seeds, plates were put in a growth chamber with standard growth condition (22°C, 100 μEinsteins light intensity and 16:8 hr light:dark cycle) except for root, heat and heat recovery plates. Root plates were placed at 4°C for 3 days before being kept vertical under standard growth condition, and heat/heat recovery plates were put in a 34°C growth chamber. After 7 days, heat recovery plates were moved to the 22°C growth chamber and cold growth plates were moved to a 10°C growth chamber.

Plates were photographed after 4 weeks (for the first round of screens on AD lines), or every week for 2 to 4 weeks starting at the 14th day after planting. The process from seed planting to the last photographing was referred as one trial. The photographs were visually assessed, and one phenotype score was assigned to each mutant line per plate based on plant size or root length (in root screen). Plants smaller than the control were considered sensitive, while plants bigger than the control were thought as tolerant. In most cases, the score is an integer

ranging from 0 to 5, with 0 representing ‘no germination’, 1 for ‘very sensitive’, 2 for ‘somewhat sensitive’, 3 for ‘normal’, 4 for ‘somewhat tolerant’, and 5 for ‘very tolerant’. In root screens, scores represented the root length, with 1 being ‘short’, 2 being ‘slightly short’, 3 being normal, 4 being ‘slightly long’, and 5 being ‘long’. When only a few (<50%) individuals within a line showed phenotypes, the score ‘seg’ (for segregating) was assigned.

For each line, average of scores at different time points was calculated. The average, in combination of the frequency of score ‘3’, was used to generate a trial score, which would be 1 (average<2.5 and no ‘3’), 2 (average<2.5 and one ‘3’), 3 (2.5≤ average ≤3.5), 4 (average>3.5 and one ‘3’), and 5 (average>3.5 and no ‘3’). The trial scores were combined to create a final score, if two trials were done. Similar scores were interpreted as an increase in the level of confidence with which sensitivity or tolerance was inferred. For example, if a mutant was assigned score 2 in both trials, then the final score would be 1. In contrast, distinctive scores were interpreted as a decrease in the level of confidence with which sensitivity or tolerance was inferred. For example, if a mutant was 1 in one trial and 3 in the other, the final score would be 2. If there was only one score for a line, that score was ‘single read’, which was not considered valid result. In OE lines, the photographs of heat screen were missing and there were all ‘single reads’ in heat recovery screen. Therefore, no results were displayed for the two screens on OE lines.

RESULTS

AD phenotypes

No soil growth phenotype was found in the AD lines of DR or control genes. In the root screen, one DR AD line (A3_11) segregated for seeds failing to germinate. A3_11 also segregated for this phenotype in every other screen, suggesting that the non-germination phenotype is not specific to root or any stress but likely to be visible under normal conditions.

Seeds which did not germinate were hard to detect in soil when a majority of the population was normal, perhaps contributing to its lack of soil growth phenotype. In addition, A3_11 seedlings were larger in the heat recovery screen and smaller in sucrose and cold growth screens (Figure 4.1) compared to WT, presumably reflecting stress-triggered aspects of its phenotype.

In four of the seven stress screens, namely, salt, sucrose, heat and cold growth, photographs were available for only one trial, in which a single sample of seedlings for each line was evaluated once per week for up to four weeks. Consequently, the results were considered preliminary. The number of phenotypes in these four screens were generally higher than the other three (ABA, mannitol, and heat recovery) (Table 4.1), possibly due to false-positive phenotypes. Nevertheless, the DR group also has more AD lines showing stress phenotype(s) than non-DR group in screens with two trials (Table 4.1), indicating that duplication of DR genes is more likely to change phenotype under stress conditions than other conserved single copy genes.

In all three stress screens with two trials, the numbers of AD lines with phenotypes were higher in DR than control, where no phenotype was detected (Table 4.1). Three DR genes had a phenotype in their AD lines, two being striking. In addition to A3_11, A1_49 was slightly sensitive in ABA screen and A2_4 was tolerant in heat recovery screen (Figure 4.1). A1_49 corresponded to a knockout phenotype, being dwarf with curled leaves, whereas no phenotype was detected in KO3_11 (SALK_076441C) and KO2_4 (SALK_027781C). Two of the three DR genes (1_49 and 2_4) had a predicted function related to transcription or translation, a major functional category in DR KO mutants revealing striking stress phenotypes, with one involved in RNA modification and the other being a transcription regulator. The remaining gene (3_11),

whose AD phenotype (non-germination) might not be stress-triggered, was a nucleoside triphosphate hydrolase.

The greater number of DR AD lines than controls with phenotypes was also evident in screens with only one trial, except heat and cold (Table 4.1) where the DR phenotype number was similar to or less than the control. This observation is consistent with the conclusion from analysis of KO lines (Chapter 3) that DR genes are not highly involved in temperature stress response. Consistency with KO analysis was also found in salt screen, in which the phenotype number was highest in DR AD lines (Table 4.1), further supporting the special correlation between salt response and duplication resistance (Chapter 3).

Unlike DR KO phenotypes, a majority of which were sensitive (Table 3.4; Table3.5), the numbers of tolerant and sensitive DR AD phenotypes (non-segregating) were similar (Table 4.2). In the control group, there were even more tolerant AD phenotypes than sensitive AD phenotypes (Table 4.2). Collectively, the available data suggested that adding an extra copy might often confer stress tolerance for Arabidopsis single copy genes that are conserved in other species.

As was seen in A1_49, AD and KO phenotypes (ABA sensitivity vs. leaf abnormality) were not necessarily connected in a direct manner. Yet for two genes, AD phenotypes were similar to knockout or knockdown phenotypes. In the DR group, both AD and KO mutants of AT3G17670 were sensitive to sucrose, indicating a possible role of this gene in sugar metabolism. In the control group, the AD and a presumed knockdown mutant of AT1G50170 (SALK_086731C, which is viable while the null mutant of the gene should be lethal) were both slightly tolerant to cold stress, suggesting its involvement in cold response in addition to being essential for plant survival [36].

OE phenotypes

There are only four control genes with OE lines, making it difficult to discern patterns differentiating these from DR genes. Therefore in this section, we focused on describing the phenotypes exhibited by DR OE lines with a brief mention of non-DR OE phenotypes.

While no soil growth phenotype was found in the four non-DR OE lines, ten of the 64 DR OE lines had soil growth phenotypes revealed by 25% or more of T1 seedlings (Table 4.3). Similar to KO mutants with soil growth phenotypes, most (seven) of the ten OE lines were 'small' (Table 4.3). Four of the small OE lines had no other mutant phenotypes, making 'small' the main category of OE soil growth phenotypes. The other equally large category is 'fertility', containing four OE lines with either reduced or no fertility. The remaining two OE lines had 'flowering' and 'leaf' phenotypes, respectively.

Five of the ten OE lines corresponded to genes with observed or published knockout or knockdown phenotypes (Table S4.1), among which one was similar to the OE phenotype. The knockdown mutant of AT3G17590 (BSH for 'bushy', a subunit of the SWI/SNF complex) is sterile [37], and its overexpression line (OE6) has reduced fertility. Among the other four genes with different KO and OE phenotypes, two proteins (NDHO and ATVPS11) are also components of protein complexes, and the other two are involved in the electron transfer chains of chloroplast and mitochondrion respectively (Table S4.1).

Despite the relatively high above ground phenotype percentage (PP), the root PP (3%) of DR OE lines and DR KO mutants (5%) were both low. The OE root phenotypes were mild and not associated with any OE soil growth phenotype. Unlike KO root mutants, half of which involved chloroplast-targeting genes (Chapter 3), neither of the two OE lines with root phenotypes corresponded to chloroplast-located proteins. OE3_36, with slightly long roots, had

slightly short roots in its corresponding KO mutant (SALK_090814C) In addition to root phenotypes, stress phenotypes were also found in KO3_36 (SALK_090814C) and OE3_36. The other OE root mutant, OE141, did not have any phenotype observed in its KO mutant. No root phenotypes were detected in non-DR OE lines.

All OE stress phenotypes were mild (scored '2' or '4') in DR and non-DR genes. The overall DR OE stress PP, defined as the percentage of OE lines showing a phenotype in at least one stress screen (45%; 29/64), was much higher than the overall DR KO stress PP (29%). A high stress PP was also found in the non-DR group, where three of the four lines had a stress phenotype. About 51% (19/37) of DR OE stress phenotypes were tolerant, whereas in DR KO mutants the tolerant phenotypes constituted of all observed stress phenotypes (Chapter 3). Similarly to KO mutants, DR OE stress PPs varied among the screens and the cold growth PP was the highest (Table 4.4).

Four DR OE lines had both stress and soil growth phenotypes (penetrance $\geq$ 25%). The remaining 25 DR genes with only OE stress phenotypes had a variety of observed KO phenotypes, including one in 'root', five in 'stress', four in 'soil growth (SG)', and two in 'potentially lethal (PL)' (Table S4.2). Among DR genes with stress-related OE and KO phenotypes, none had a predicted function directly pointing to stress signaling. Instead, three were unknown and two were related to transcription or translation regulation (Table S4.3). OE and KO phenotypes were similar for two DR genes (AT1G01920 and AT1G62250): OE79 and KO79 (SALK_060683C) were sensitive in the salt screen, and OE100 and KO100 (SALK_065936) were sensitive in the cold growth screen. In contrast, the other three DR genes showed OE and KO phenotypes in different stress screens, suggesting that they might participate

in multiple stresses' pathways or processes that were not directly related to stress but weakened plant in general once disturbed.

Removing those with OE soil growth phenotypes (penetrance>=25%), there were 29 DR genes with no observed OE phenotype. Fourteen of the 29 DR genes had observed KO phenotypes, half of which were PL and the other half stress related (Table 4.5; Table S4.4). Compared to genes with observed OE phenotypes, the proportion of KO PL phenotypes was higher in genes without observed OE phenotypes, while the proportion of KO soil growth phenotypes was much lower (Table 4.5). This observation also held true for published KO phenotype data (Table 4.5), indicating that the severity of KO phenotypes was not positively correlated with the likelihood of having OE phenotypes in DR genes.

AD phenotypes seemed to be more similar to OE phenotypes than KO phenotypes of the same genes. AD and OE phenotypes appeared in the same stress screen in four of the five genes (AT2G20980, AT1G56345, AT1G63980, AT1G50170) for which phenotypes were detected in both AD and OE lines, while only two genes showed KO and OE phenotypes in the same stress screen. Interestingly, OE phenotypes were not severe versions of AD phenotypes in the four genes. Both AD and OE phenotypes were slightly tolerant (score '4') in two genes, while the AD phenotype was slightly tolerant and OE phenotype was slightly sensitive (score '2') in the other two genes.

DISCUSSION

The persistent single copy status of some genes, herein called DR genes, has long been puzzling to evolutionary biologists. To unveil the basis of duplication resistance, which represents important mechanisms for gene and genome evolution, a thorough understanding of DR genes' function will be extremely helpful, if not absolutely necessary [13] (Chapter 3).

Among the various approaches for gene function analysis, we previously investigated knockout (KO) mutants, the phenotype screens of which constituted the initial phase of our research on DR genes. In the present stage, Arabidopsis AD and OE lines were made and phenotyped, to further advance functional investigation and test empirically whether DR genes confer a fitness reduction when present in more than one copy or expressed at a high level. The phenotypic features of these lines, as summarized and explained below, shed new light on this unique population of plant genes and their choice to stay single.

No soil growth phenotype was observed in DR AD lines, indicating that extra copies of these genes generally do not confer a drastic change. This finding was expected, because given that hundreds of DR genes exist, if the duplication of most DR genes resulted in visible morphological alternation, the newborn polyploid species would die quickly. Instead, the duplication effect is more likely to be mild, compatible with our observation, or take numerous generations to accumulate to a detectable level. The mild effect of an extra copy may be more visible on population level than on individual plant. For example, duplication of a DR gene may confer disadvantage in competition with other plants, causing continuous decrease in frequency of plants with the duplicated gene in a population. These possibilities could be tested by methods designed for revealing subtle phenotypes or by multigenerational study that has been used in knockout mutants [38].

More AD phenotypes were found in DR genes than in other single copy genes, consistent with the expectation that duplication of DR genes is more likely to affect phenotype than non-DR singletons. Interestingly, some DR AD lines showed mild stress tolerance. Most mild tolerant phenotypes came from stress screens with only one trial, thus needing further validation. However, the appearance of a striking tolerant phenotype (A2_4) in such a small sample implies

that the duplication of some DR genes may indeed confer stress tolerance. Much further testing is needed to determine if a mild degree of stress tolerance, superficially seeming to be a potential fitness advantage, translates into increased or decreased overall seed output. Functions mitigating stresses in unfavorable environments sometimes do more harm than good in optimal environments, where their consistent activation may compromise normal growth and reproduction. Indeed, increased expression of stress tolerance genes has been reported to cause reduced stature or fitness [39, 40]. Such adverse effects, though perhaps individually mild, may add on one another and be intensified in a genome duplication event.

Similar to the findings from our KO phenotype study, genes that may affect transcription or translation dominated the promising stress-response candidates identified in AD or OE lines. Among the two genes with striking AD stress phenotypes, one is involved in DNA or RNA metabolism and the other is annotated as a transcription regulator. Though no OE stress phenotype is striking, five genes with both OE and KO stress phenotypes have known annotations (RNA modification and SET domain protein) related to transcription or translation. Therefore, in this broad functional category of DR genes, some may serve as good targets for molecular breeding of crops with improved stress tolerance.

Seedling phenotypes with greater than or equal to 25% penetrance occurred in ten DR OE lines, making the phenotype percentage (15.6%) higher than that of DR HM KO lines (9.2%). Though ‘small’ remains a main feature for these OE lines, no pigment phenotype was detected, despite the fact that five of the ten proteins are located in chloroplast. In combination with previous results (Chapter 3), chloroplast-targeting DR genes tend not to cause pigment abnormality in either KO or OE lines. Instead, they affected a wide range of processes including root or leaf development, stress response and reproduction. On the other hand, ‘fertility’ was a

large subgroup of OE soil growth phenotypes, containing four OE lines with reduced fertility. Little or no fertility, found in 30% of 1262 activation-tagging lines revealing a phenotype [41], seems to be one of the major outcomes of Arabidopsis gene overexpression. Therefore, whether DR genes are more prone to fertility (and fitness) reduction than other genes upon overexpression remains unknown, requiring testing of more OE control genes.

Genes possessing both OE and KO phenotypes, compromising about one third of the DR gene sample with OE lines, show behavior that is consistent with dosage sensitivity. For this fraction of DR genes, dosage sensitivity may have contributed to their persistent single copy status, as gene removal and gene duplication are associated with dosage change. Three of the five dosage sensitive proteins (BSH, NDHO and ATVPS11) with OE soil growth phenotypes were components of protein complex (Table S4.1). Moreover, most (six of nine) DR genes encoding subunits of protein complexes are dosage sensitive (Table S4.5), supporting what would be predicted from the dosage balance hypothesis [42]. In contrast, only a small proportion (28%; 10/36) of chloroplast or mitochondrion targeting DR genes are dosage sensitive (Table S4.6), a finding not compatible with the notion that they are in dosage balance with their organelle genome-encoded partners [14, 23]. Although the test sample is small, the frequency of AD phenotypes seems to be lower in organelle-targeting DR genes (50%; 3/6) than other sampled DR genes (80%; 4/5), suggesting that neither dosage increase nor gene duplication in this DR subset is prone to cause immediate harm. Instead, the long term existence of a duplicated copy may be problematic. For example, mutations accumulated on the regulatory or coding sequence of either copy may interrupt the normal functioning of the pathway in which the gene participated.

The respective effects of knockout and overexpression are neither similar nor opposite in most cases. Genes with OE soil growth phenotypes have various KO phenotypes, including those detectable only on biochemical level, stress sensitivity and lethality (Table S4.1). Likewise, a wide range of KO phenotypes were found in genes with OE stress phenotypes. Different KO and OE phenotypes of the same gene occurred in non-DR genes as well, suggesting that such incongruity is a general phenomenon rather than a feature specific to DR genes. The chance of showing OE phenotypes differs among genes in distinct KO phenotype groups: all sampled DR genes with soil growth KO phenotypes have OE phenotypes, while only a minority of DR samples with potentially or confirmed lethal KO mutants cause detectable phenotypes when overexpressed. Therefore, mechanisms other than dosage sensitivity may be responsible for the duplication resistance of essential DR genes. For example, their functions, representing perhaps the most fundamental metabolic steps, might be unable to split into subfunctions and lack the potential to evolve novelty, rendering the duplicated copies useless.

A few genes had OE and KO phenotypes observed in the same screen, relating their functions to root growth, fertility, or a particular stress. The opposite root phenotypes in OE3_36 and KO3_36 suggested that root growth was promoted by the overexpression of AT1G56345 and retarded at its knockout. Being a pseudouridine synthase, AT1G56345 may positively regulate the translation of genes that induce root growth. Of the three genes where the KO and OE phenotypes were similar, one (AT_3G17590) was implicated in stoichiometry, the disturbance of which by knockout and overexpression may affect the same process thus exert similar phenotypic effect [18]. Given the intricacy of stress signaling network, however, perturbation on different functional pathways can lead to the same phenotype. The expression profile may be distinctive in the KO and OE lines of AT1G01920, a SET domain protein, yet

some of the transcriptional changes in both lines may lead to salt sensitivity. The correlation of AT1G62250's function with cold response, on the other hand, serves as a starting point to study this unknown gene. Collectively, these OE phenotypes helped to point out or narrow down a realm of possibilities that future functional studies could focus on.

In addition to providing insights on duplication resistance and gene function, the abundance of AD and OE phenotypes shows these lines to be practical tools in investigating the effects of duplication and overexpression of DR genes. Application of OE and especially AD lines in a larger gene sample is expected to reveal more phenotypes, which may help to validate the previous findings and lead to new discoveries. Further, analysis other than phenotype screens could be done using available AD or OE plants. Through evaluating the expression of key growth or stress signaling regulators in some promising lines, we might be able to connect DR genes with known pathways, thus providing more clarity on their functions. The possible consequence of having a mutation-bearing duplicated copy can be visualized via plants transformed with artificially mutated AD constructs. AD or OE constructs could also be transformed into other plant species, for extensive functional study of DR genes. Together, the plant and phenotype resources described here, along with the transgenic constructs, will contribute to future investigation in related research areas.

Table 4.1 Number of AD lines with phenotype(s). Heatrec stands for ‘heat recovery’. Coldgro stands for ‘cold growth’.

	Screens with two trials					Screens with one trial					
	ABA	**Mannitol**	**Heatrec**	**Root**	**Overall[1]**	**Salt**	**Sucrose**	**Heat**	**Coldgro**	**Overall[2]**	**Overall[3]**
DR	2	1	2	1	3	4	3	1	2	6	7
Control	0	0	0	0	0	1	1	2	2	5	5

1. Number of AD lines with phenotype in at least one of the ABA, mannitol, heat recovery and root screens; the number remains the same without the root screen.

2. Number of AD lines with phenotype in at least one of the salt, sucrose, heat and cold growth screens.

3. Number of AD lines with phenotype in at least one of the eight screens; the number remains the same without root screen.

Table 4.2 Number of sensitive, tolerant, and segregating phenotypes. Sensitive phenotypes are with score 0, 1 or 2. Tolerant phenotypes are with score 4 or 5. Seg stands for ‘segregating’.

	Screens with two trials				**Screens with one trial**				
	Sensitive	**Tolerant**	**Seg**	**Total[1]**	**Sensitive**	**Tolerant**	**Seg**	**Total[2]**	**Total[3]**
DR	1	1	4	6	3	4	2	9	15
Control	0	0	0	0	1	5	0	6	6

1. The sum of 'sensitive', 'tolerant' and 'seg' in screens with two trials (excluding root screen).

2. The sum of 'sensitive', 'tolerant' and 'seg' in screens with one trial.

3. The sum of 'sensitive', 'tolerant' and 'seg' in all stress screens.

Table 4.3 Soil growth phenotypes of DR OE lines. Penetrance equals to the percentage of T1 plants showing a phenotype.

Mutant_ID	Gene	Penetrance	Category	Description
OE2	AT1G74880	25%	small	small
OE6	AT3G17590	73%	fertility	Reduced fertility
OE46	AT3G09580	50%	small	small
OE49	AT5G48440	42%	small	small
OE66	AT2G05170	67%	fertility	small and purple; no seeds
OE120	AT2G43400	75%	flowering	large, late flowering
OE122	AT2G46060	75%	small	very small
OE128	AT3G09210	>90%	fertility	small, sterile
OE161	AT4G30840	25%	fertility	small, sterile
OE162	AT4G31460	>50%	leaf	wavy and curled leaves

Table 4.4 Total number of DR OE lines and phenotype percentages in each stress screen. Total number of OE lines is the number of OE lines with a valid phenotype score. Coldgro stands for 'cold growth'.

	ABA	**Mannitol**	**Salt**	**Sucrose**	**Coldgro**
Total number of OE lines	61	61	61	62	63
Phenotype percentage	7%	0%	16%	15%	22%

Table 4.5 Proportions of genes with KO phenotypes in OE lines with and without phenotypes. Observed KO phenotypes are from our previous KO phenotype screen (Chapter 3). Published KO phenotypes are from Lloyd and Meinke's dataset [1] and other publications regarding to specific genes. ESN stands for essential. MRP stands for morphological (detailed in [1])

OE lines	**Observed KO phenotypes**				**Published KO phenotype[1]**	
	PL	**Soil growth**	**Root**	**Stress**	**ESN**	**MRP**
with phenotype	0.06	0.11	0.06	0.17	0.06	0.23
without phenotype	0.21	0.00	0.00	0.21	0.14	0.07

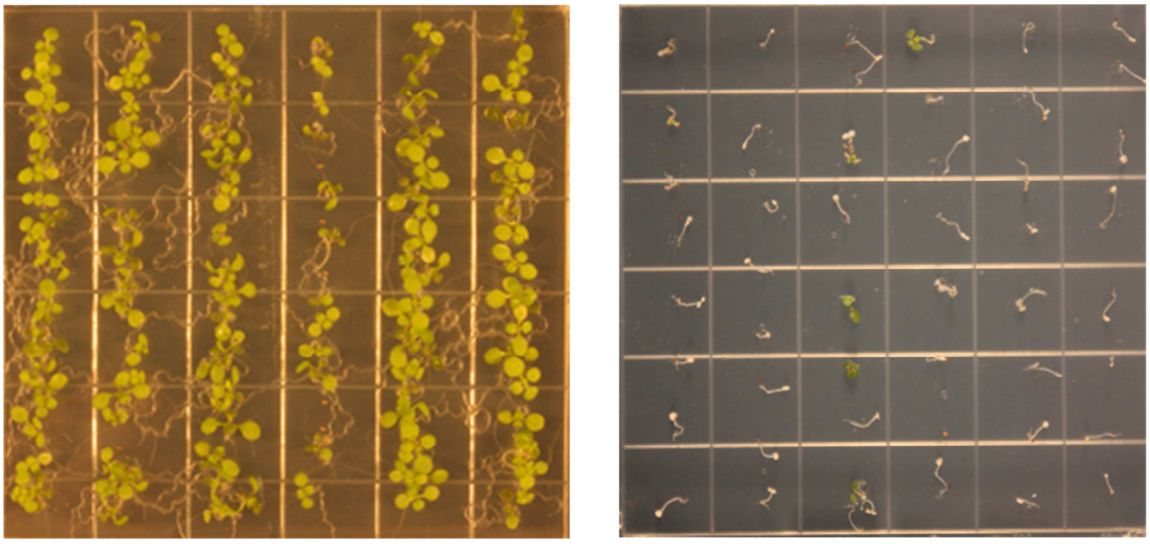

Figure 4.1 Phenotypes of AD lines. Left figure shows A3_11 in cold growth screen. Right figure shows A2_4 in heat recovery screen.

CHAPTER 5

CONCLUSION

In this study, stress and root phenotype screens were conducted on three genotypes of DR genes, namely, knockout mutant (KO), addition (AD) and overexpression (OE) lines, in order to better understand DR gene functions and to investigate their duplication and dosage increase effects. The KO and AD lines of some randomly selected non-DR Arabidopsis single copy genes were also screened for phenotypes, as controls.

A variety of phenotypes, including seedling phenotypes under normal conditions, were found in KO mutants (SALK lines) of DR genes. Of the intended screens, including drought (ABA, mannitol), salt, sucrose, heat, heat recovery, cold growth, cold germination, and root screens, KO mutant phenotypes were detected in all but one (heat recovery). Plants grown on soil for genotyping and fresh seed production also exhibited various phenotypes. For SALK lines with T-DNA insertion but no HM plant detected, two thirds had phenotypes suggesting lethality. Accordingly, our observed KO phenotypes were divided into four main categories: stress, root, soil growth, and potentially lethal (PL).

The percentage of mutant lines showing phenotypes, referred to as phenotype percentage (PP), is used to compare the KO phenotypes of DR genes and controls. Unlike what public datasets suggested, our direct observations find DR genes to have higher percentages of potentially lethal and soil growth phenotypes than other singletons (‘OT’ in Chapter 1). Therefore, it is possible that DR genes are relatively more important to Arabidopsis than other singletons.

The stress PP of DR genes is lower than the primary control group (SCR), and similar to a supplemental control group (nDR), suggesting that DR genes are not highly involved in response to the tested stresses. Rather than reacting to environmental stimuli, DR genes may tend to have housekeeping functions, the disturbance of which might cause phenotypes more severe than those visible only under stress conditions. This hypothesis is supported by higher proportions of PL and soil growth phenotypes in DR genes than other singletons. Alternatively, DR genes' KO mutants might be more responsive to stresses causing DNA damage, such as UV light and γ-ray, which would be an intriguing screen to pursue in further study.

Compared to the control group, DR genes had lower proportions of ABA and cold sensitive phenotypes, suggesting less involvement in ABA-mediated stress signaling and lack of cold positive regulators. In contrast, salt phenotypes were only found in DR genes, and did not co-occur with mannitol phenotypes, indicating that DR genes tend to function in response to the non-osmotic component of salinity stress. IT is not yet clear if, or how, these phenotypic features may be related to duplication resistance.

DR genes that may affect transcription or translation of other genes, for example, transcription regulator or those involved in DNA or RNA metabolism, had a high knockout PP. Chloroplast –targeting DR genes, on the other hand, were slightly less likely to have phenotypes upon knockout than other DR genes. Chloroplast-targeting DR genes corresponded to various KO phenotypes, and occurred at a high frequency in phenotype categories such as root, sucrose and cold germination.

It is expected that some of our observed phenotypes were different from published loss-of-function phenotypes of the same genes, whose root or stress phenotypes may not have been previously screened for. Inconsistency between observed and published phenotypes for some

genes may come from non-target T-DNA insertions, or knockdown mutants, in which the more severe published phenotypes were absent. As the published phenotypes were usually confirmed by expression analysis, different alleles or complementary test, mutants used in our study were likely to be knockdown. Therefore, further validation of our observed phenotypes is necessary, though the observed phenotypes should remain true for the SALK lines used in this study.

AD lines, made by transforming the cloned genomic region of the target genes into Col0 Arabidopsis, were used to attempt to visualize gene duplication effects. Due to the small number of genes with AD lines and the similar sample sizes of DR and the control, phenotype number, defined as the number of mutants with phenotypes, was used to compare AD phenotypes of DR and control genes. DR genes have a higher phenotype number than control genes, indicating that DR genes are more likely to cause a visible change upon duplication than other singletons.

No soil growth phenotype was detected in AD lines, suggesting that the effect of gene duplication is normally weak. Striking stress phenotypes of AD lines, including one stress tolerance phenotype, were found in the DR group but not in the control group. The appearance of stress tolerance phenotypes in such a small sample of DR AD lines was intriguing from a practical standpoint and indicates that duplication of some DR genes may lead to better vegetative growth under stress conditions, but whether their duplication improves reproductive performance remains unknown.

OE lines, in which the transgenic constructs contain cDNAs under the control of the 35S promoter, were expected to reveal the consequences of large gene dosage increase. Soil growth phenotypes were found in DR OE lines at a higher frequency than DR KO lines, with the main features being small stature and reduced fertility. Half of genes with OE soil growth phenotypes had no KO phenotype, suggesting that OE lines would be useful in functional study of genes

without KO phenotypes. The other half of genes with OE soil growth phenotypes correspond to various KO phenotypes that are not limited to seedling alternations, reflecting different OE and KO effects of the same DR genes. Indeed, genes with OE stress phenotypes have a wide range of KO phenotypes as well.

About a third of DR genes with OE lines have both KO and OE phenotypes, indicating that some DR genes are dosage sensitive. Dosage sensitivity may have contributed to duplication resistance, as gene removal and duplication are accompanied by dosage change. Such dosage sensitivity at the phenotype level was found in genes that are predicted to be dosage sensitive. Most DR genes encoding components of protein complexes revealed phenotypes in their KO and OE lines, while the proportion of chloroplast-targeting DR genes with KO and OE phenotypes was slightly lower than one third.

Validation of associations between phenotypes and the intended gene duplication or overexpression is an important next step. AD and OE phenotypes may not always be caused by duplication and overexpression, respectively. For example, the transgene constructs may be located in other genes, revealing KO phenotypes that are unrelated to the target genes. Or, co-supression may have happened, reducing gene product. Though no evidence suggests that these situations occurred frequently, some of the observed phenotypes will inevitably be proved artifactual during the validation process.

Nevertheless, the abundant AD and OE phenotypes suggest that DR genes can have immediate, visible duplication and overexpression outcomes, which may be an important next step in understanding the basis of duplication resistance. In addition to detailed examination of AD/OE lines with phenotypes, such lines could be created for more genes and studied in various ways. In summary, our results mark one step toward better understanding of DR genes'

biological functions, and accordingly toward the basis of single-copy dosage regulation. The trends observed in this study provide several worthwhile future research directions, and show that more exciting discoveries can be made using the largely unexplored mutant collection.

Table S3.2 SALK lines genotype results. Green cells in column 'Gene' represent genes with two SALK lines. HM stands for 'homozygous'. HT stands for 'heterozygous'. WT stands for 'wildtype'. The numbers in column 'HM', 'HZ', and 'WT' are the numbers of plants with corresponding genotypes.

Mutant_ID	Gene	Gene group	SALK	Insertion position	HM	HT	WT	Genotype group

Table S3.3 Observed and published phenotypes for PL SALK lines. In column 'Published phenotypes', ESN stands for 'essential', MRP stands for 'morphological', NOP stands for 'no obvious phenotype'. More detailed information regarding to these phenotype categories (ESN, MRP) can be found in Lloyd and Meinke, 2012 (cited in Chapter 3 main text).

mutant_ID	Gene	Group	Observed phenotype			Published phenotype
			On soil	Heterozygous siliques	Stress and root screen	
106	AT1G73350	DR	turned albino at 4 leaf stage			
130	AT3G10572	DR	tiny	small seeds		ESN
134	AT3G15180	DR	reduced fertility			
144	AT3G51820	DR				MRP
145	AT3G56210	DR	small			
149	AT3G60850	DR				
159	AT4G27750	DR	1/4 small and dying			MRP

Table S3.4 Soil growth phenotypes for HM SALK lines. In column 'Observed phenotype', 'YG' stands for 'yellow green', 'VLF' stands for 'very late flowering', 'RF' stands for 'reduced fertility'. Descriptions in column 'Published phenotype' came from references listed after this table or Lloyd and Meinke, 2012 (cited in Chapter 3 main text).

Mutant_ID	Gene	Observed phenotype			Published phenotype		
		Mutant	Phenotype	Category	Mutant	Phenotype	Group
107	AT1G76250	SALK_019804	YG, lethal	lethal			
11	AT3G25470	SALK_043556C	small, YG , early flowering	flowering			
115	AT2G22370	SALK_027178C	small curled leaves and YG; #11 VLF and no seed, #5 large leaves and RF; #8 small; #12 wt	multiple	SALK_027178[1]	cause a syndrome of related phenotypes affecting flowering time, inflorescence structure, and flower morphology.	MRP
122	AT2G46060	SALK_135304C	small lethals, retest	lethal			
127	AT3G09180	SALK_012449	small, dark green	pigment			
128	AT3G09210	SALK_039502	embryo lethals, retest	lethal			
13	AT4G00560	SALK_138740C	small, YG	pigment			
131	AT3G13940	SALK_054381	abnormal seeds	seed			
135	AT3G20070	SALK_148785	embryo lethals; #s10,11,12 fewer siliques, slightly smaller	seg	a non-SALK T-DNA insertion line (Syngenta)[2]	Embryo defective; Preglobular; Enlarged endosperm nuclei	ESN
160	AT4G29890	SALK_026428	small , YG	pigment			
177	AT5G11030	SALK_089074	seg small and abnormal	seg	SALK_063183[3]	defective in lateral root formation; fail to respond to exogenous IAA;	MRP
26	AT5G20600	SALK_073773C	small, silvery leaves	leaf			
34	AT1G61690	SALK_133410C	small, lethal	lethal			
40	AT5G15390	SALK_005531C	fewer leaf trichomes	leaf			
51	AT1G04130	SALK_073054C	YG, dying	pigment			
97	AT1G48270	SALK_027808	seg 32:8 for tiny seedlings	seg	CS540[4]	Abolishes Seed Dormancy; Enhances the Expression of Germition-Associated Genes; Accelerates Flowering and the Expression of Genes that Control Flowering.	MRP
99	AT1G60600	SALK_021962C	YG, lethal	lethal	Feldmann T-DNA line, no. 2755[5]	Seedling lethal without exogenous sucrose; Abnormal chloroplast development	ESN
PD7	AT4G21770	SALK_149232C	many small leaves	leaf

Table S3.10 HM SALK lines without observed phenotypes and with published phenotypes.

Mutant_ID	Gene	Our mutant	Mutant with published phenotypes	Published phenotype description
6	AT3G17590	SALK_073635C	RNAi line	Plants with >=80% of the WT mRNA didn't have any phenotype; Plants with <=15% mRNA were bushy.[1]
44	AT5G23290	SALK_057848C	CT955299	smaller than WT; sensitive to 100mM NaCl; slightly sensitive to 12mM LiCl and 300mM Mannitol[2]
86	AT1G10830	SALK_068653C	SALK_136385, CS859876, SALK_057053, and SALK_057915C	defect in greening after transfering from dark to light[3]
88	AT1G12790	SALK_127447C	SALK_127447	shorter siliques; a portion of flowers have less pollens; [4]
111	AT2G04270	SALK_093546C	SALK_093546	albino on agar plates; albino seedings on soil [5]
120	AT2G43400	SALK_007870	SALK_007870	shorter siliques and lower number of seeds[6]
132	AT3G14110	SALK_002383C	flu; T-DNA insertion mutant, not SALK	growth inhibition after transferring from dark to light[7]
157	AT4G18470	SALK_018281	EMS mutant	much smaller than WT[8]
163	AT4G34700	SALK_030356	SALK_097732	late flowering at 40 days; looks smaller (not very striking but visible) than WT at 8 week; shorter root (not quite striking)[9]
220	AT1G77320	SALK_201730C	Versailles collection of T-DNA lines	very short silique and very few seeds (1.5 per silique); seeds slightly larger than WT[10]

Table S3.13 Number and percentage of chloroplast-targeting (CT) genes in DR genes with stress phenotypes in each screen.

	ABA	Mannitol	Salt	Sucrose	Heat	Heatrec	Coldgro	Coldger
Number of DR genes with phenotypes	8	4	7	11	3	0	10	3
Number of CT DR genes with phenotypes	3	0	1	5	0	0	2	3
Percentage of CT DR genes	38%	0%	14%	45%	0%	NA	20%	100%

Table S3.14 Phenotype comparison among three published datasets. The three published datasets, '4000DS', 'Hanada' and 'Lloyd and Meinke' were introduced in Chapter 2. Column 'Gene' includes genes involved in both 4000DS and Hanada datasets. 'NP' stands for 'no phenotype'. 'NA' stands for 'not available'. Other letters in 'Phenotype Group' are abbreviations of phenotype categories: the ones in '4000DS' and 'Hanada' can be found in Hanada et al., 2009 (cited in Chapter 3 main text) , and those in 'Lloyd and Meinke' can be found in Lloyd and Meinke, 2012 (cited in Chapter 3 main text).

Additional table S4.1-S4.6

Table S4.1 Genes with OE soil growth phenotype and a KO phenotype.

Mutant_ID	Gene	Protein description	OE phenotypes	KO phenotype
OE2	AT1G74880	subunit NDH-O of NAD(P)H:plastoquinone dehydrogenase complex (Ndh complex) present in the thylakoid membrane of chloroplasts. This subunit is thought to be required for Ndh complex assembly.	small	no postillumination fluorescence transient; low sensitivity to antimycin A (AA); lack of shifted AG emissio[1]
OE6	AT3G17590	Encodes the Arabidopsis homologue of yeast SNF5 and represents a conserved subunit of plant SWI/SNF complexes	Reduced fertility	sexual sterility in addition to a characteristic "bushy" phenotype[2]
OE46	AT3G09580	FAD/NAD(P)-binding oxidoreductase family protein	small	Slightly sensitive in ABA screen
OE66	AT2G05170	Homologous to yeast VPS11. Forms a complex with VCL1 and AtVPS33. Involved in vacuolar biogenesis. The mRNA is cell-to-cell mobile.	small and purple; no seeds	poentially lethal (small seeds in heterozygous silique)
OE120	AT2G43400	ELECTRON-TRANSFER FLAVOPROTEIN:UBIQUINONE OXIDOREDUCTASE, ETFQO; Encodes a unique electron-transfer flavoprotein:ubiquinone oxidoreductase that is localized to the mitochondrion. Mutants are more sensitive to sugar starvation when plants are kept in the dark for long periods.	large, late flowering	shorter siliques and less seeds; Early senescence in the dark[3]
